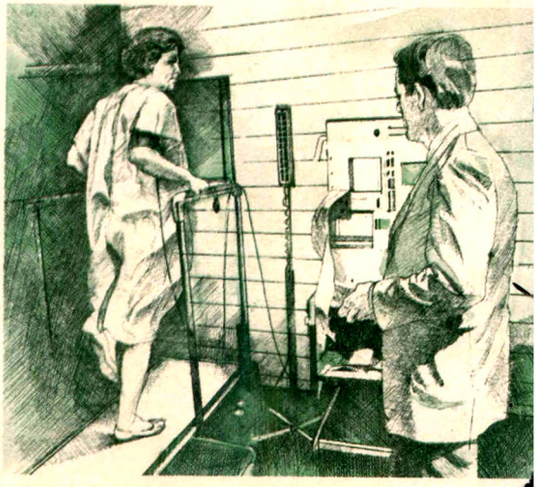
ANSWERS ABOUT ALDOMET® (METHYLDOPA|MSD)

Will an antihypertensive generally allow a normal cardiovascular response to exercise?

Cardiac output and blood pressure normally increase with increasing physical activity. ALDOMET does not significantly impair normal fluctuations of blood pressure during exercise.[1,2]



In a recent study of hypertensive patients whose cardiovascular response to exercise was evaluated before and during methyldopa therapy, "...methyldopa significantly reduced the rise in systolic pressure during the build-up ($P<0.01$) and subjective maximal stages ($P<0.05$) as well as at all phases of recovery ($P<0.01$)." Moreover, "The total duration of exercise (an index of work capacity) was unchanged with...methyldopa."[3]

Such findings can be of importance to active hypertensive patients such as the athletic individual or the person whose work requires substantial physical effort. For these and many other hypertensive patients, ALDOMET represents a logical therapeutic choice.

With ALDOMET, exercise hypotension rarely occurs. Sedation, usually transient, may occur during the initial period of therapy or whenever the dose is increased. Headache, asthenia, or weakness may be noted as early and transient symptoms.

ALDOMET® offers many (METHYLDOPA|MSD) other important features:

- Highly effective in all degrees of hypertension.
- Existing cardiac output is usually maintained.
- Renal blood flow is usually maintained.
- Has documented long-term efficacy.
- Significant adverse effects have been infrequent and the agent is usually well tolerated.

ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, and if previo methyldopa therapy has been associated with live disorders. It is important to recognize that a positiv Coombs test, hemolytic anemia, and liver disord may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unles properly recognized and managed.

MSD
MERCK SHARP DOHME

For hypertension—

ALDOMET®
(METHYLDOPA | MSD)

The most prescribed nondiuretic antihypertensive in the U.S. today

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression.

Cardiovascular: Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.)

Gastrointestinal: Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis.

Hepatic: Abnormal liver function tests, jaundice, liver disorders.

Hematologic: Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor.

Allergic: Drug-related fever, lupus-like syndrome, myocarditis.

Other: Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets, containing 125 mg methyldopa each, in bottles of 100; Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000; Tablets, containing 500 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 500.

MAC

More than an ECG... Sensitivities up to 400 times that of standard ECG machines

The High Resolution Amplifier Option for MAC gives you the capability of recording extremely low amplitude, high frequency ECG components by amplifying signals up to 400 times that of standard electrocardiographs. The signal averaging technique employed effectively attenuates noise without distortion of the ECG signal. In the final report, selected ECG leads are shown at three different gains and four frequency bands. Switch selectable options allow the operator to select abnormal or intermittent beats for averaging and adjust the output to suit various applications.

MAC's innovative microprocessor detects an corrects AC interference and baseline dr optimally positions the trace and automa ically initiates a rhythm strip whe arrhythmias are present. By monitorin common problems, MAC does th quality control before ECG's are recorde or transmitted. State-of-the art microcon puter technology allows new developmen to be implemented without extensi hardware changes. Other available optio include Digital Recording and Transmissio and Pacemaker Evaluation Progra

In Hypertension*...

Every Step of the Way

Each capsule
contains 50 mg. of
Dyrenium® (brand of triamterene)
and 25 mg. of hydrochlorothiazide.

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F Co. literature or *PDR*. A brief summary follows:

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K^+ frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

To prevent predictable angina*

CHEWABLE SORBITRATE®

(ISOSORBIDE DINITRATE) 5 mg. or 10 mg.

dependable, prolonged protection during periods of emotional or physical exertion.

Summary Of Prescribing Information

* **Indications:** Based on a review of this drug by The National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: The chewable dosage form of SORBITRATE is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.

Precautions: Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE* (isosorbide dinitrate) may be taken for prompt relief of angina pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.

Onset of Effect: Two to five minutes.

Duration of Effect: One to two hours.

STUART PHARMACEUTICALS
Division of ICI Americas Inc.
Wilmington, DE 19897

For patients who need K^+Cl^- one sparkles bright:

KLORVESS® EFFERVESCENT GRANULES offer SPARKLING FAST DISSOLUTION

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

- **ready in *seconds* instead of minutes —fast dissolution so unique it's patented***
- **pleasant citrus flavor**
- **each packet delivers 20 mEq of potassium and chloride**
- **easily carried in patient's pocket or purse**
- **can be mixed with water or other liquid for pleasant daily dosage**
- **sugar, sodium, carbohydrate and dye free**

Give your patients the KLORVESS sparkle

Please see brief summary of prescribing information on adjoining page.

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

The original dipyridamole.

Persantine®
(dipyridamole)

INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and /or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine tablets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.

ADVERSE REACTIONS— Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25 mg and 75 mg

CLINICAL STUDIES

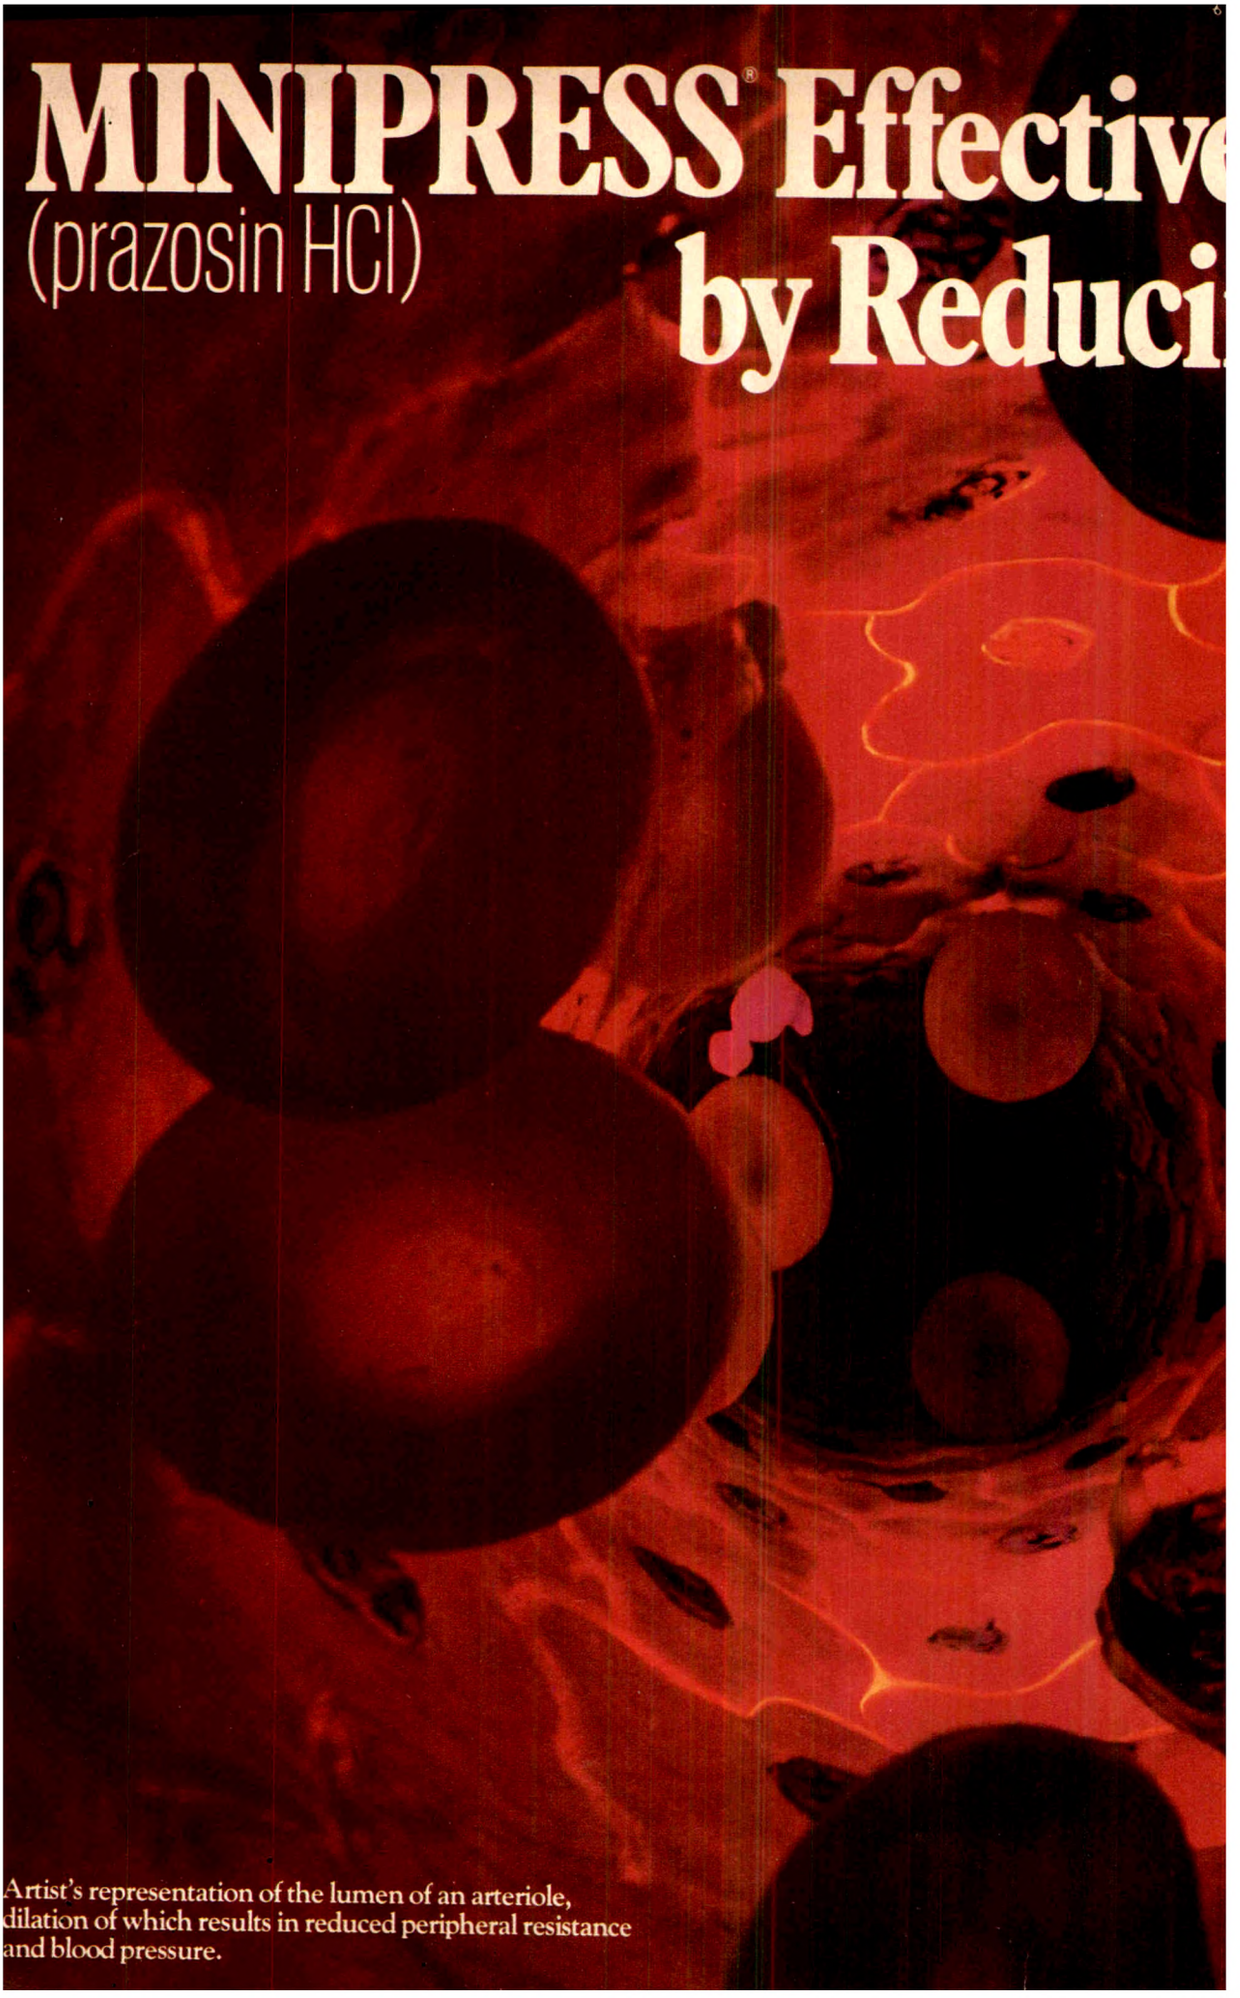
535 **Absence of Correlation Between Coronary Arterial Atherosclerosis and Severity or Duration of Diabetes Mellitus of Adult Onset**

VINCENT J. VIGORITA, G. WILLIAM MOORE and GROVER M. HUTCHINS

Correlation of the clinical and autopsy data in 185 patients with diabetes mellitus of adult onset suggests that the progression of atherosclerotic disease is unrelated to the duration or severity of the diabetes, but the larger coronary arteries in the diabetic patients are subject to more atherosclerosis than are those in nondiabetic subjects. The diabetic patients also showed an increase in angiographically determined number of diseased coronary vessels, diffuseness of coronary disease and collateralization of coronary arteries. The severity of diabetes mellitus predicted only retinopathy. These results indicate that the progress of larger vessel coronary atherosclerotic disease in diabetes mellitus of adult onset takes place independently of the progress of the diabetes itself.

543 **Clinical and Arteriographic Variables Predictive of Survival in Coronary Artery Disease**

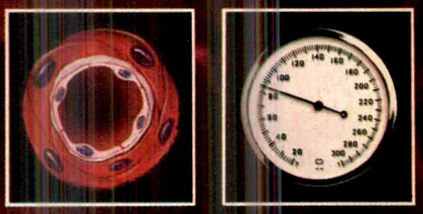
EDWARD V. PLATIA, LOUISE GRUNWALD, E. DAVID MELLITS, JOHN O'NEAL HUMPHRIES and LAWRENCE S. C. GRIFFITH



Utilizing multivariate stepwise discriminate function analysis in 90 nearly consecutive patients who underwent coronary arteriography at The Johns Hopkins Hospital between 1960 and 1961, these investigators identified the following three independent predictors of mortality: (1) the simultaneous occurrence of a narrowing in the left anterior descending and right coronary arteries; (2) prior myocardial infarction; and (3) 70 percent or greater narrowing proximal to the first anterior descending septal branch. When included, a "positive" stress electrocardiographic test also proved an independent predictor of mortality. Survival analysis showed the poorest outcome in patients with a 70 percent or greater narrowing in the proximal left anterior descending artery and a positive stress test and the best outcome in patients with similar arterial narrowing but a negative stress test.

553 **Merits of Stress Thallium-201 Myocardial Perfusion Imaging In Patients With Inconclusive Exercise Electrocardiograms: Correlation With Coronary Arteriograms**

ABDULMASSIH S. ISKANDRIAN, LOUIS A. WASSERMAN, GARY S. ANDERSON, HAMID HAKKI, BERNARD L. SEGAL and SALLY KANE



In this study of 65 patients with an inconclusive exercise electrocardiogram, exercise thallium-201 scintigraphy had a specificity of 97 percent, a sensitivity of 70 percent, a predictive positive value of 95 percent and a predictive negative value of 82 percent. With this technique the investigators were able to predict the correct diagnosis in 56 (86 percent) of the 65 patients with an inconclusive exercise electrocardiogram. In such patients exercise thallium-201 imaging appears to be more reliable when the images are abnormal than when they are normal. The high specificity and predictive accuracy of this noninasive method could reduce the need for coronary arteriography in patients with an inconclusive exercise electrocardiogram for coronary heart disease.

Controls Hypertension Peripheral Resistance

- MINIPRESS Reduces Mean Arterial Pressure
- MINIPRESS Reduces Total Peripheral Resistance
- MINIPRESS Does Not Reduce Cardiac Index

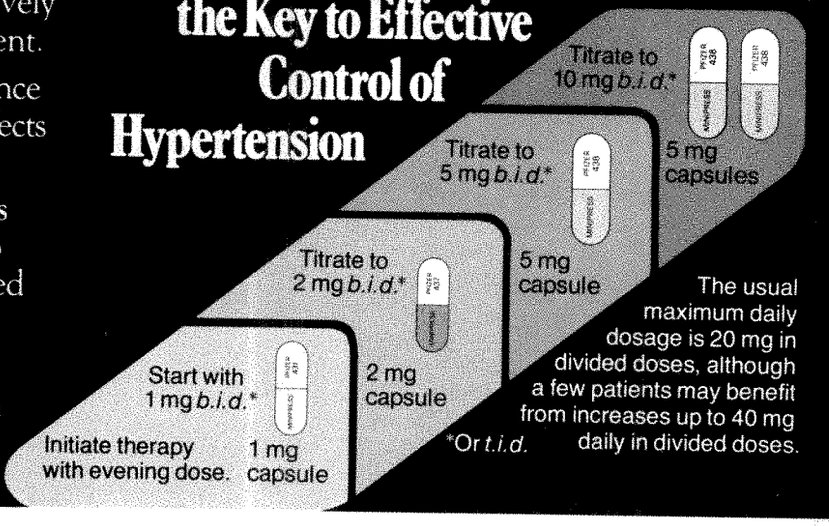
...and Maintains These Effects Over the Long Term

Relative hemodynamic changes at rest and during exercise after one year of prazosin therapy in 10 hypertensive patients. Adapted from Lund-Johansen[1]

Rest Exercise

MINIPRESS®

(prazosin HCl)



Capsules 1 mg, 2 mg, 5 mg

Please see Brief Summary on last page. © 1989 Pfizer Inc.

MINIPRESS®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

- **Effectively lowers elevated blood pressure** by reducing peripheral resistance.
- **Maintains cardiac output** which allows patients to maintain an active life style.
- **Maintains renal blood flow and glomerular filtration rate** so it can be used effectively even in patients with renal impairment.
- **Not a CNS agent** so patients experience few of the troublesome CNS side effects that impair their quality of life.
- **Cardiovascular response to exercise is preserved** so patients are less likely to experience the fatigue often associated with beta-blocker therapy.
- **A small percentage of patients** have experienced orthostatic hypotension and syncope.

B.I.D. Dosage Titration... the Key to Effective Control of Hypertension

The usual maximum daily dosage is 20 mg in divided doses, although a few patients may benefit from increases up to 40 mg daily in divided doses.

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, incontinence, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy, however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

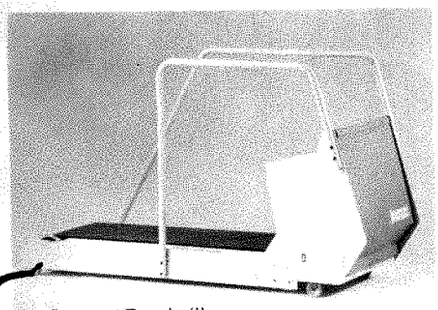
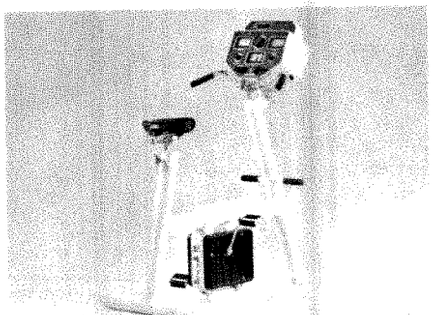
Pfizer LABORATORIES DIVISION
PFIZER INC.



He might be running for his life

Whether he's in a cardiac conditioning, diagnostic or rehabilitation program, your patient deserves the best in exercise equipment. At Collins, we've been making the best for sixty years. From our first treadmill to our newest Pedalmate ergometer, each product has been developed to meet the Collins standard of excellence — innovative design, durable construction and easy operation.



The result has been a continuing tradition of superior instruments that reflect not only the latest technology, but a concern for patient comfort and safety as well. Each treadmill features handrails, a large usable walking area and a new fiberglass fabric-coated surface under the belt to minimize friction and wear. Our four treadmills offer speed ranges up to 16 mph and electric lift from 0-40%. For precise manual or automatic heart rate control capabilities, the Pedalmate combines the convenience of an exercise bicycle with the choice of either a 25-200 or 50-400 watt brake unit.

High quality plus performance — it all adds up to product integrity that has made Collins the first choice for over half a century. So when you need exercise equipment, choose Collins. You'll be sure of the best for your patient — and yourself. Write today for our latest catalog.

559 **Pathogenesis of Paroxysmal Hypertension Developing During and After Coronary Bypass Surgery: A Study of Hemodynamic and Humoral Factors**

RONALD WALLACH, ROBERT B. KARP, J. G. REVES, SUZANNE OPARIL, LLOYD R. SMITH and THOMAS N. JAMES

Fifteen (54 percent) of 28 patients manifested new hypertension with increased peripheral vascular resistance and unchanged cardiac output within 1 hour after surgery. An elevation in plasma epinephrine and norepinephrine concentration, suggesting enhanced sympathoadrenal responsiveness to the challenge of cardiopulmonary bypass, was characteristic of the hypertensive group. Patients with severe angina of prolonged duration, well preserved ventricular myocardium and coronary anatomy suitable for more than three saphenous vein bypass grafts tend to become hypertensive postoperatively. The pathophysiologic mechanism of sympathetic activity in patients with new hypertension after saphenous vein bypass surgery remains uncertain.

566 **Early Results With Composite Strut Caged Ball Prostheses**

QUENTIN MACMANUS, GARY GRUNKEMEIER, LELAND HOUSMAN, CHRISTOPHER MALONEY, BRADLEY HARLAN, LOUIS LAMBERT and ALBERT STARR

Experience with 270 operative survivors of mitral valve replacement with the model 6400/10 prosthesis and 240 operative survivors of aortic valve replacement with a model 2400/10 prosthesis, all on continuous anticoagulant therapy, indicates that cloth wear and hemolysis have not been significant problems with this prosthesis. The rates of thromboembolism are comparable with those reported for xenograft bioprostheses. The composite strut valve is a durable alternative to the glutaraldehyde-preserved porcine xenograft valve in patients who are able to tolerate anticoagulant therapy.

570 **Genesis of Pericardial Knock in Constrictive Pericarditis**

THEODORE I. TYBERG, ALLAN V. N. GOODYER and RENE A. LANGOU

Supported by data from left ventriculograms, phonocardiograms and external pulse recordings in seven patients with hemodynamic and pathologic findings of constrictive pericarditis and in seven normal subjects, these investigators were able to relate pericardial knock to an abrupt plateau in the diastolic left ventricular volume curve. This relation was evident in five patients with constrictive pericarditis and the knock but absent in two patients with pericarditis and no knock. These data support the view that sudden cessation of ventricular filling generates the pericardial knock of constrictive pericarditis. Although the precise mechanism by which the sudden limitation of ventricular filling in constrictive pericarditis is converted to the sound of the pericardial knock remains to be clarified, a "water-hammer" effect or a "sail-flop" phenomenon may be responsible.

576 **Initiation and Termination of Ventricular Tachycardia by Supraventricular Stimuli. Incidence and Electrophysiologic Determinants as Observed During Programmed Stimulation of the Heart**

HEIN J. J. WELLENS, FRITS W. BÄR, JERÓNIMO FARRÉ, DAVID L. ROSS, ISAAC WIENER and EDGARD J. VANAGT

Ventricular tachycardia could be initiated by a single ventricular premature stimulus during ventricular pacing in 43 patients and in 7 (16 percent) of these same 43 patients by a single atrial premature stimulus during atrial pacing. All seven patients showed a right bundle branch block configuration of the QRS complex and a relatively slow rate during the tachycardia. In one patient a conducted atrial premature stimulus terminated the ventricular tachycardia. This study suggests that formation of an abnormal impulse at the supraventricular level may play a more important role than previously realized in the initiation of ventricular tachycardia and that in some patients initiation of ventricular tachycardia by a conducted supraventricular impulse will occur only if the premature impulse is aberrantly conducted through the ventricle.

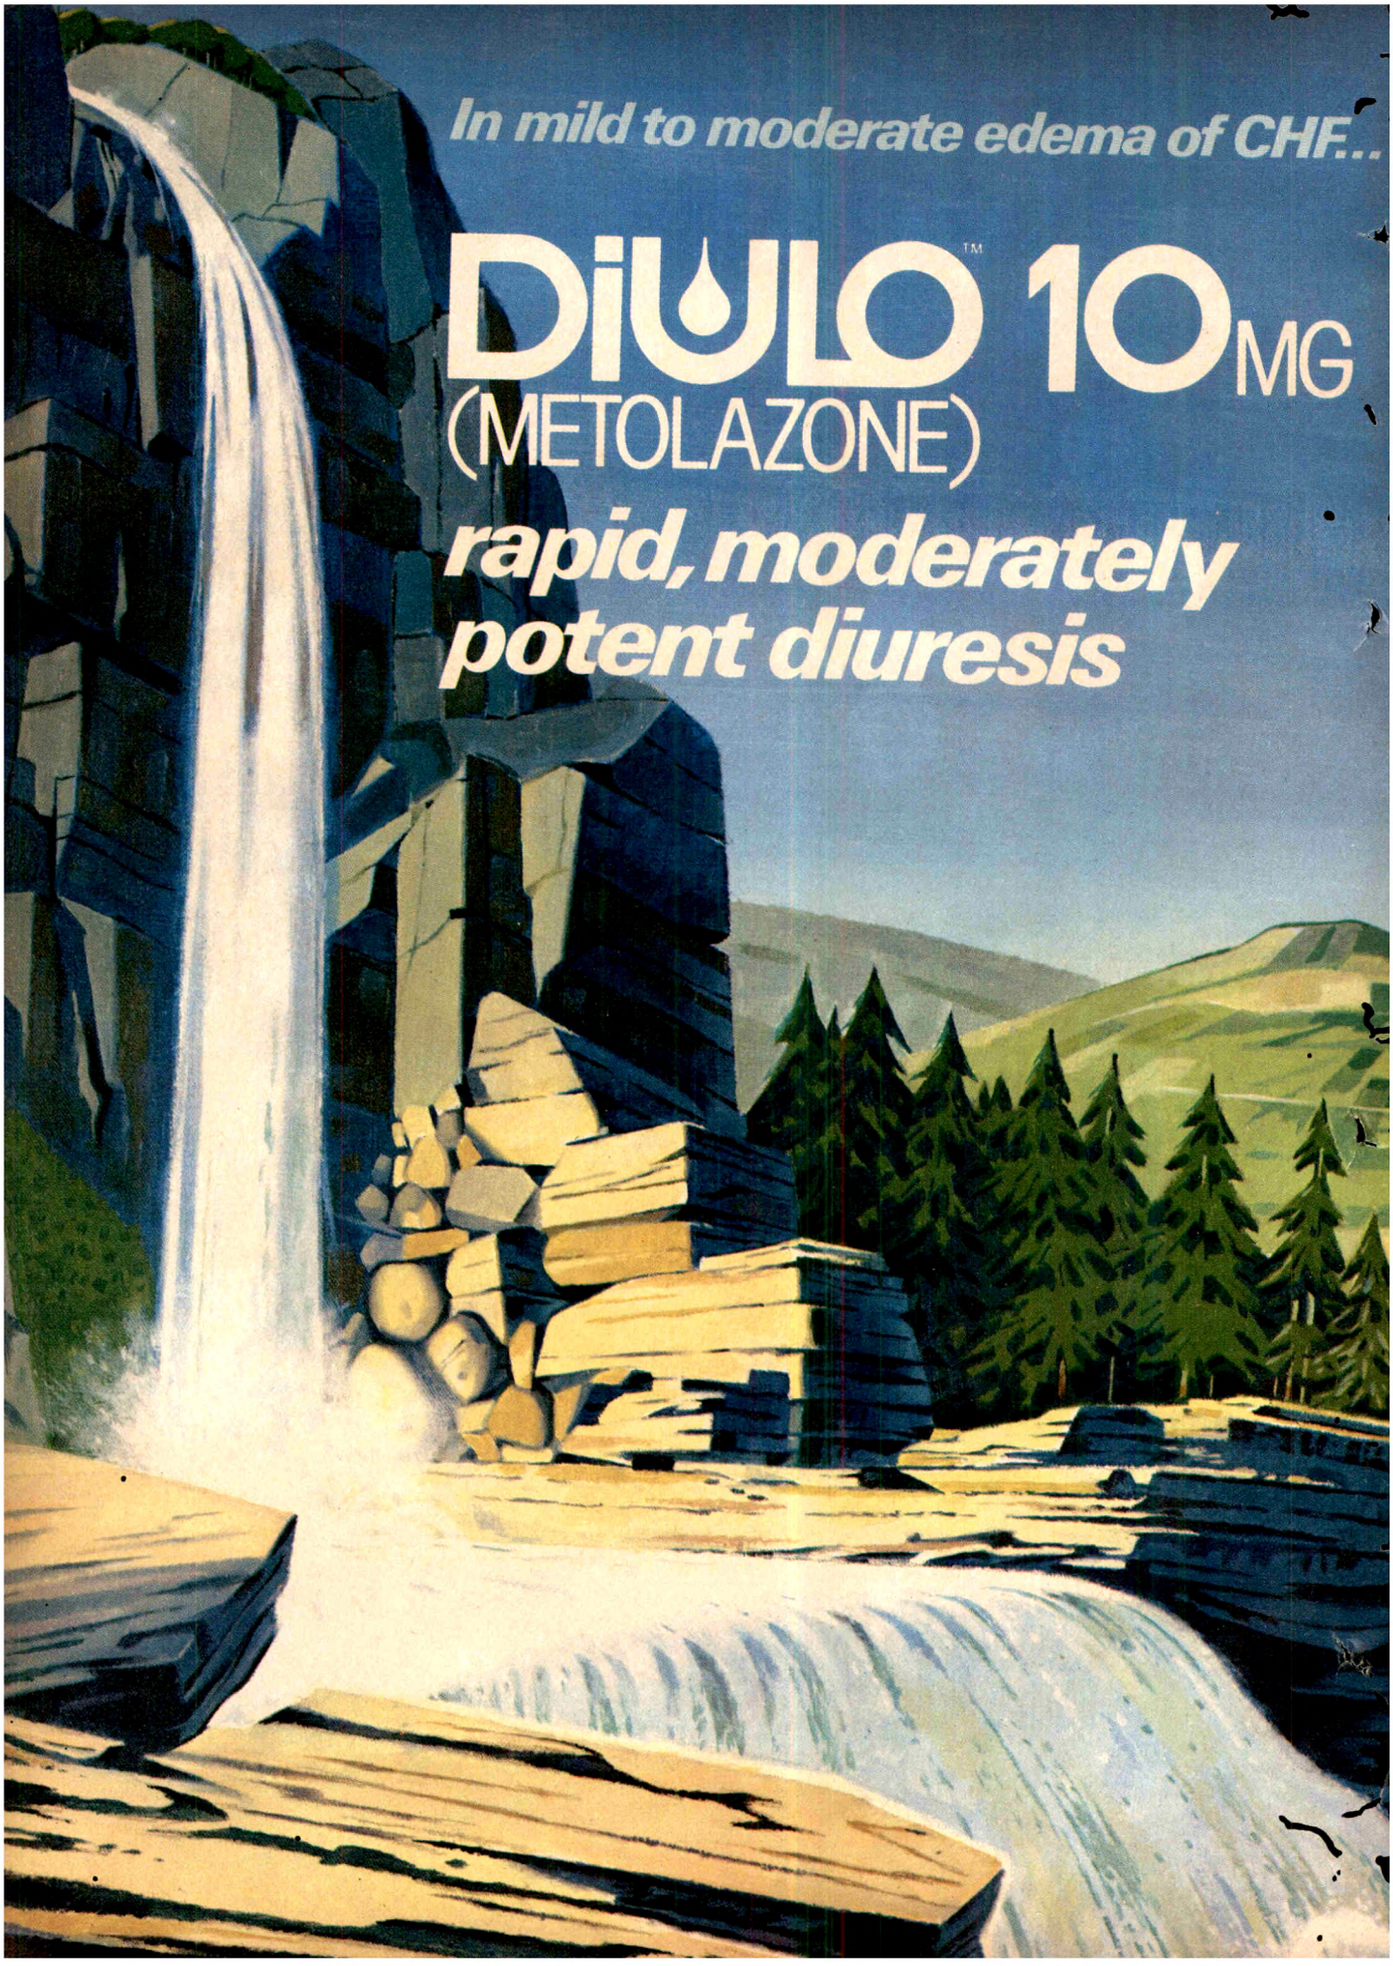
No one exercise tolerance system is right for everyone...

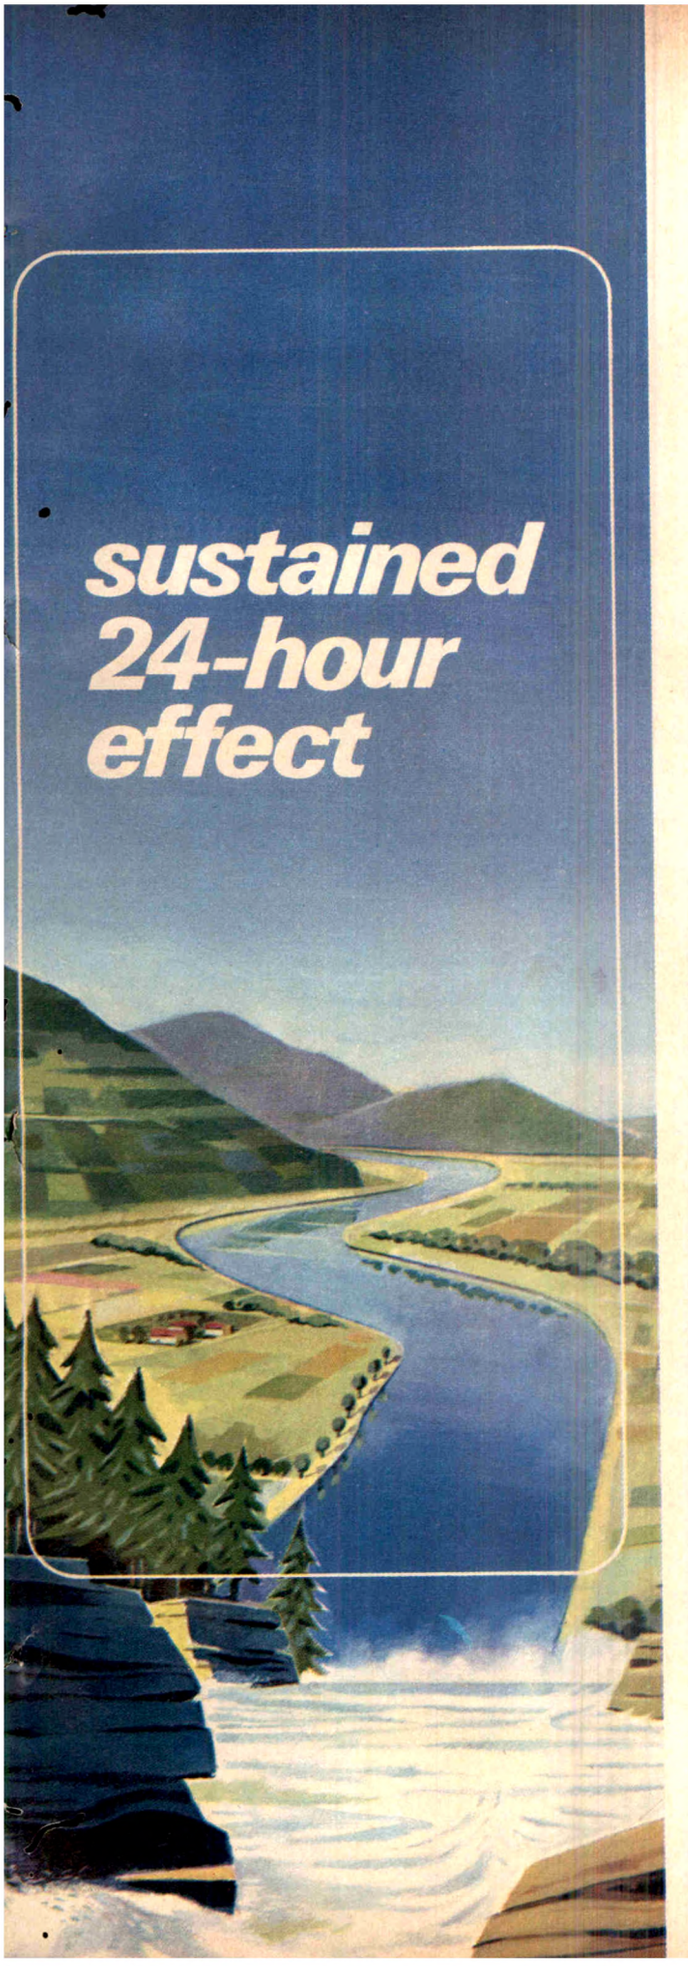
which is why Burdick offers a choice.

Like any other professional instrumentation, an exercise tolerance system can be right for one physician and something less (or more) for another. The right choice depends on your practice, preferred protocols, staff, budget, and other considerations.

That's why Burdick offers a choice of ExTOL™ systems to match your needs, without resorting to a combination of components that lack the instrument compatability and one-source serviceability of a Burdick ExTOL system.



We offer three basic exercise tolerance systems with a wide choice of options—single or three-channel cardiographs, single or multi-channel monitors, defibrillators, and our economical TMS-400 or deluxe TMS-300 treadmill with remote control and programmer. In short, we have an ExTOL system that's right for your practice, your particular needs.



For complete information about ExTOL, or a demonstration, call or write
The Burdick Corporation, Milton, Wis. 53563.

BURDICK

A concern for cardiac care.

In mild to moderate edema of CHF...
DIULO™ 10 MG
(METOLAZONE)
rapid, moderately
potent diuresis

Diulo (metolazone) 10mg Indicated for use in chronic CHF

In acute pulmonary edema, dramatic volume depletion is desirable. That's why agents capable of producing profound diuresis within a few hours are indicated. But where smooth, prolonged effect is desirable – as in patients with chronic CHF, whether they be bedridden and elderly, ambulatory, or have low GFRs – a single, oral, therapeutic dose of Diulo produces effective natriuresis for up to 24 hours.

With Diulo 10 mg, your patient with chronic CHF benefits from effective diuretic action. But unlike those receiving more potent diuretics, patients receiving Diulo are not "wrung out" in two or three hours.

Although the conditions of some patients can be adequately controlled with a 5-mg dose of Diulo, one 10-mg tablet daily can provide effective diuresis around the clock in your patients with CHF, including those with paroxysmal nocturnal dyspnea.

DIULO™ (metolazone) 2½-mg., 5-mg. and 10-mg. tablets *Before prescribing, see complete prescribing information. The following is a brief summary:* ***Indications:*** *Diulo (metolazone) is an antihypertensive diuretic indicated for the management of mild to moderate essential hypertension as sole therapeutic agent and in the more severe forms of hypertension in conjunction with other antihypertensive agents. Also, edema associated with heart failure and renal disease.* ***Contraindications:*** *Anuria, hepatic coma or precoma; allergy or sensitivity to metolazone.* ***Warnings:*** *In theory, cross-allergy may occur in patients allergic to sulfonamide-derived drugs, thiazides or quinethazone. Hypokalemia may occur, and is a particular hazard in digitalized patients; dangerous or fatal arrhythmias may occur. Azotemia and hyperuricemia may be noted or precipitated. Considerable potentiation may occur when given concurrently with furosemide. When added to other antihypertensives, the dosage of the other agents should be reduced. Use with potassium-sparing diuretics may cause potassium retention and hyperkalemia. Administration to pregnant women or those of childbearing age requires that potential benefits be weighed against possible hazards to the fetus. Metolazone appears in the breast milk. Not recommended for pediatric use.* ***Precautions:*** *Perform periodic examination of serum electrolytes, BUN, uric acid, and glucose. Observe patients for signs of fluid or electrolyte imbalance, hyponatremia, hypochloremic alkalosis and hypokalemia. These determinations are particularly important when there is excessive vomiting or diarrhea, or when parenteral fluids are administered. Patients treated with diuretics or corticosteroids are susceptible to potassium depletion. Caution should be observed when administering to patients with gout or hyperuricemia or those with severely impaired renal function. Insulin requirements may be affected in diabetics, and hyperglycemia and glycosuria may occur in latent diabetes. Chloride deficit and hypochloremic alkalosis may occur. Orthostatic hypotension may occur. Dilutional hyponatremia may occur.* ***Adverse Reactions:*** *Constipation, nausea, vomiting, anorexia, diarrhea, bloating, epigastric distress, intrahepatic cholestatic jaundice, hepatitis, syncope, dizziness, drowsiness, vertigo, headache, orthostatic hypotension, excessive volume depletion, hemoconcentration, venous thrombosis, palpitation, chest pain, leukopenia, urticaria, other skin rashes, dryness of mouth, hypokalemia, hyponatremia, hypochloremia, hypochloremic alkalosis, hyperuricemia, hyperglycemia, glycosuria, raised BUN or creatinine, fatigue, muscle cramps or spasm, weakness, restlessness, chills, and acute gouty attacks.* ***Usual Initial Once-Daily Dosages:*** *Mild to moderate essential hypertension – 2½ to 5 mg.; edema of cardiac failure – 5 to 10 mg.; edema of renal disease – 5 to 20 mg. Dosage adjustment is usually necessary during the course of therapy.* ***How Supplied:*** *Tablets, 2½, 5 and 10 mg.; in bottles of 100 and 500, and cartons of 100 unit-dose individually blister-sealed tablets.*

EXPERIMENTAL STUDIES

583 Kinetics of Antifibrillatory Effects of Bretylium: Correlation With Myocardial Drug Concentrations

JEFFREY L. ANDERSON, EUGENE PATTERSON, MARILYN CONLON, STANISLAW PASYK, BERTRAM PITT and BENEDICT R. LUCCHESI

These data confirm the excellent antifibrillatory effects of bretylium in the dog heart and emphasize the importance of tissue pharmacokinetics in determining its behavior. Serum bretylium concentration decreased rapidly after intravenous injection, whereas myocardial concentrations increased gradually, peaking at 1.5 to 6 hours in both open and closed chest dogs. Electrophysiologic and antifibrillatory effects paralleled myocardial rather than serum drug kinetics with peak effects at 3 to 6 hours. The average increase in the ventricular fibrillation threshold exceeded 12-fold after administration of 6 mg/kg of the drug (2 minutes to 12 hours). These results suggest a need during the clinical use of this drug for repeated acute drug dosing and allowance of greater time after acute bretylium administration before assuming drug failure.

593 Myocardial Effects of Long-Term Cigarette Smoking: Relative Roles of Carbon Monoxide and Nicotine

S. SULTAN AHMED, CHRISTOS B. MOSCHOS, HENRY A. OLDEWURTEL and TIMOTHY J. REGAN

In this well designed beagle study the effects of long-term cigarette use on the myocardium appear to depend predominantly on nicotine rather than on carbon monoxide. Carboxyhemoglobin did not differ among beagles smoking three cigarettes of low or high nicotine content, either in the immediate postsmoking or late period. In dogs smoking low nicotine cigarettes for 18 months there were no abnormalities of myocardial performance or composition. The nicotine users exhibited a significant decrease in diastolic compliance during volume expansion, a decrease in the basal contractility indexes and increases in the collagen content of the myocardium. Serum lipids were unchanged in the long-term smokers and in the group receiving nicotine.

599 Electrophysiologic Effects of Imipramine and Doxepin on Normal and Depressed Cardiac Purkinje Fibers

F. JAMES BRENNAN

In this study the direct electrophysiologic actions of imipramine and doxepin on isolated canine Purkinje fibers are shown to be similar. Moderately depressed fibers are more sensitive than normal fibers to certain of these effects. Both imipramine and doxepin reduced conduction velocity and failed to alter the refractory periods of the depressed fibers whereas at the same concentration in normal fibers they caused no change in conduction velocity but shortened the refractory periods. The different incidence rates of arrhythmias and conduction disturbances associated with their clinical use is probably not due to differences in their direct electrophysiologic effects on the ventricular specialized conduction system, but may be due to the generally lower plasma drug levels in patients receiving doxepin than in those receiving imipramine.

METHODS

607 Transcutaneous Method of Measuring Doppler Cardiac Output—I. Comparison of Transcutaneous and Juxta-aortic Doppler Velocity Signals With Catheter and Cuff Electromagnetic Flowmeter Measurements in Closed and Open Chest Dogs

JOHN R. DARSEE, J. RONALD MIKOLICH, PAUL F. WALTER and ROBERT C. SCHLANT

This study of 20 closed and open chest dogs demonstrates the usefulness of the transcutaneous Doppler method of measuring cardiac output by multiplying the 1 minute sum of Doppler velocity integrals in systole by the cross-sectional area of the proximal aorta. The results showed a close similarity between Doppler signals and electromagnetic waveforms and a close similarity between Doppler and thermodilution values for cardiac output except at heart rates above 160 beats/min. Application of this method to clinical use in human beings, although promising, requires further study to develop a method for measuring the cross-sectional area of the aorta and accounting for systolic change.

continued on page A26

You May Be Mis-Diagnosing Your Holter Patients.

The incompleteness of Holter scan reports with unverifiable numbers and trends are the reasons. Less than 1% of the Holter ECG data is normally presented for your diagnosis. What happened the other 99% of the time?

1979 brought a breakthrough in Holter monitoring. The development of micro-computer controlled fiberoptics made it possible to print every ECG complex into a textbook format, providing twenty-four, hourly pages of ECG data.

No matter who the operator, the report is identical every time, and only takes three minutes to generate. Plus, this report is faster and easier to read than that of conventional Holter equipment.
The major difference is "Assurance".

The product is The Eliminator™ by AdvanceMed, now a part of American Hospital Supply Corporation. The Eliminator is the first to offer 100% accurate ECG data and is available at half the price of average Holter equipment.

You owe it to yourself and to your patients to see The Eliminator. Since it is compatible with most Holter recording systems, call or write and we'll run one of your tapes.
You May Be Surprised To See What You Are Missing!

American Edwards / AdvanceMed, 1923 SE Main Street, Irvine, California 92714, (714) 751-1824. (800) 854-8081.

TO 4½ MILLION HYPERTENSIVE PATIENTS, THIS IS USUALLY THE ONLY SIGN THAT INDERAL® IS WORKING.

(PROPRANOLOL HCl)

A modest reduction in pulse rate: usually the first sign that INDERAL is at work.

Mode of action, yes. Side effect, no. Because it is generally accepted that even heart rates as low as 50 to 55 beats per minute, in otherwise asymptomatic patients, are not usually a cause for concern. The real side effects* associated with INDERAL occur so infrequently that today over 4½ million hypertensive patients are doing well on regimens built around INDERAL.

To their physicians, the signs are even more encouraging...

because INDERAL, alone or in combination with other agents, has established a remarkable record of blood pressure control. Another encouraging sign: increased dosage usually does not produce proportional decreases in heart rate.

Proper patient selection is important: INDERAL should be employed only in the absence of congestive heart failure, sinus bradycardia, or heart block greater than first degree.*

But in most patients, the initial signs of its effect will be reflected in subsequent signs of effectiveness: significantly lowered blood pressure.

Effective in b.i.d. dosage

For most patients twice-daily dosing of INDERAL is effective in maintaining blood pressure reduction throughout the day. Some patients on lower doses may experience a modest rise in blood pressure at the end of a 12-hour interval. Larger doses, or t.i.d. dosing, should re-establish control.

At the heart of well-tolerated antihypertensive therapy

INDERAL®

(PROPRANOLOL HCl)

B.I.D.

FOR HYPERTENSION

40 mg and 80 mg tablets

*Please see the following page for brief summary of prescribing information on warnings, including avoidance of abrupt withdrawal, contraindications, and adverse reactions.

P24, 120

INDERAL® (PROPRANOLOL HCl)

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR)
Inderal® BRAND OF
propranolol hydrochloride
A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS

The mechanism of the antihypertensive effects of INDERAL has not been established. Among the factors that may be involved in the antihypertensive action are (1) decreased cardiac output; (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain.

Propranolol hydrochloride decreases heart rate, cardiac output, and blood pressure. Although total peripheral vascular resistance may increase initially, it readjusts to the pretreatment level, or lower, with chronic usage. Earlier studies indicate that plasma volume remains unchanged or may decrease. However, there are certain more recent studies suggesting that in the absence of sodium restriction, plasma volume may increase.

INDICATIONS

Hypertension
INDERAL is indicated in the management of hypertension. It is usually used in combination with other drugs, particularly a thiazide diuretic. INDERAL is not indicated for treatment of hypertensive emergencies.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.*, that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis; erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DOSAGE AND ADMINISTRATION

ORAL

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 40 mg INDERAL twice daily, whether used alone or added to a diuretic. Dosage may be increased gradually until adequate blood pressure is achieved. The usual dosage is 160 to 480 mg per day. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower doses are used, may experience a modest rise in blood pressure toward the end of the 12 hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or 3 times daily therapy may achieve better control.

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

INTRAVENOUS

The intravenous administration of INDERAL has not been evaluated adequately in the management of hypertensive emergencies.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg). IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS.

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.

HOW SUPPLIED

INDERAL
(propranolol hydrochloride)

TABLETS

No. 461—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 462—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 464—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 468—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

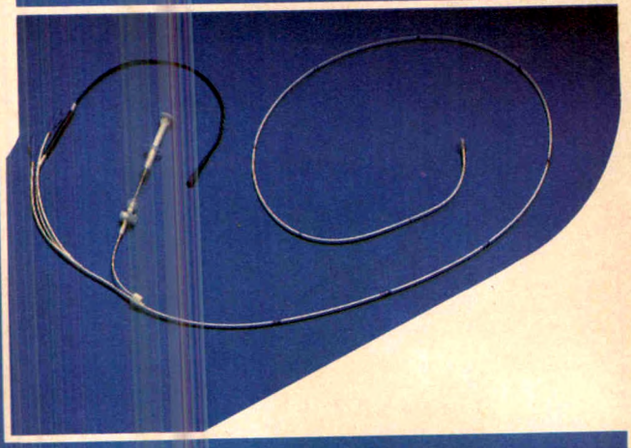
Ayerst AYERST LABORATORIES
New York, N.Y. 10017

CAVITRON'S "ALL IN TWO" SOLUTION for measuring CARDIAC OUTPUT.

CAVITRON™

OXYGEN CONTENT ANALYZER OC-60



$$1.\ \dot{Q} = \frac{\dot{V}O_2}{CaO_2 - C\bar{v}O_2}$$

- ☐ Use the Classic Fick Standard — O_2 Content of Blood and Gas
- ☐ Measure O_2 Content — **Don't** Estimate It
- ☐ Use Smaller Blood Samples — 20 μL
- ☐ Believe O_2 Content — 0.99 Correlation with Van Slyke

A TRUE 7F THERMAL DILUTION CATHETER

- ☐ Reduce Introduction Trauma — use a **7F** introducer
- ☐ Receive Accurate Blood Pressure — Large distal lumen means better frequency response
- ☐ Believe Cardiac Output — A single one percent (1%) thermistor means accuracy

THERMAL DILUTION CARDIAC OUTPUT COMPUTER TD-75

$$2.\ \dot{Q} = \frac{Vi\,(T_B - T_i)\,(1.08)\,(k)\,(60)}{\int_0^{\infty} T_B\,(t)\,(dt)}$$

- ☐ Accurate Cardiac Output — Uses Stewart Hamilton Exponential Method, not a fudge factor
- ☐ Know When to Believe the Computer — Automatic fault indication and curve validation
- ☐ Use Consistent Technique — Auto Injector is standard
- ☐ Accurate While Easy To Use — Designed to use Room Temp Injectate

613 **Transcutaneous Doppler Method of Measuring Cardiac Output—II. Noninvasive Measurement by Transcutaneous Doppler Aortic Blood Velocity Integration and M Mode Echocardiography**

JOHN R. DARSEE, PAUL F. WALTER and DONALD O. NUTTER

Noninvasive measurement of cardiac output by transcutaneous Doppler aortic blood velocity integration and M mode echocardiography is useful and practical for measuring changes in cardiac output in patients with acute myocardial infarction. Results are poorer at heart rates exceeding 150 beats/min. Advantages of the Doppler method over catheterization techniques for the repeated measurement of cardiac output include the use of a single unit on multiple patients, none of the risks of indwelling catheters, no necessity for blood samples or expansion of the intravascular volume, greater safety, and availability for use by nurses and technicians.

619 **Improved Diagnostic Accuracy of Thallium-201 Stress Test Using Multiple Observers and Criteria Derived From Interobserver Analysis of Variance**

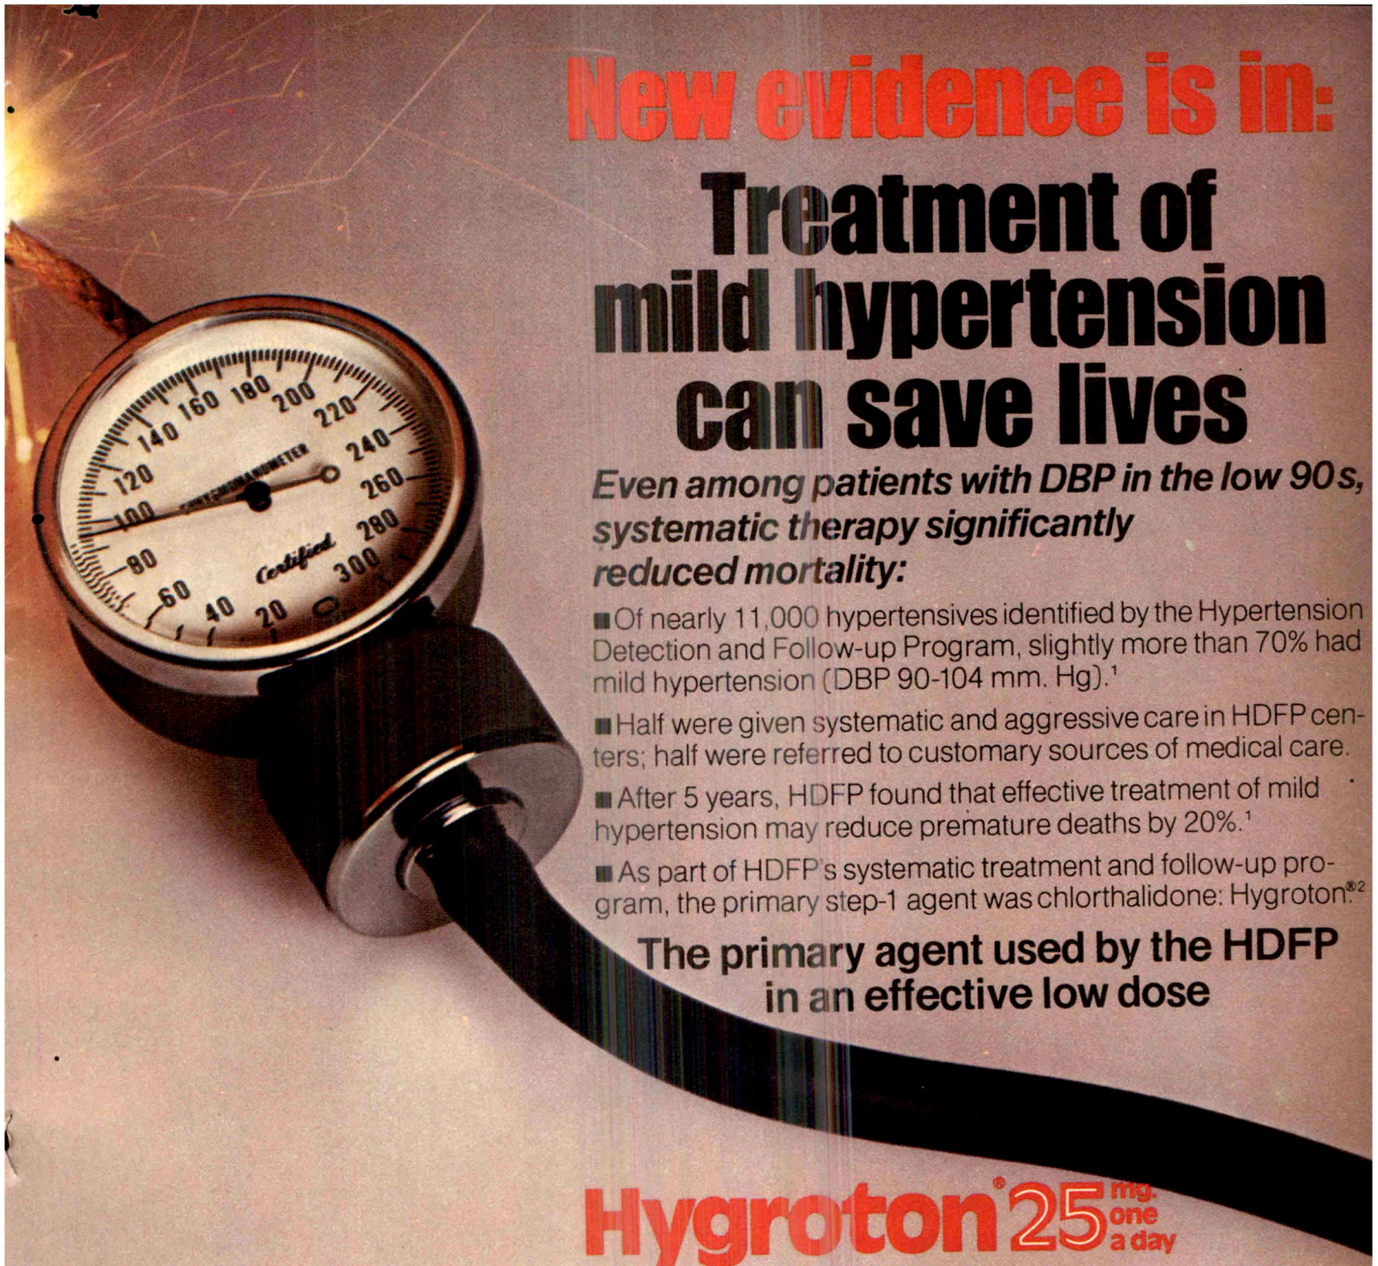
ROBERT D. OKADA, CHARLES A. BOUCHER, HOWARD K. KIRSHENBAUM, FRED G. KUSHNER, H. WILLIAM STRAUSS, PETER C. BLOCK, KENNETH A. McKUSICK and GERALD M. POHOST

These results demonstrate considerable interobserver variance in the overall interpretation of the thallium stress test. Use of the standard criteria and four observers produced complete agreement on the overall diagnosis in 58 percent, partial agreement in 26 percent and complete disagreement in 16 percent of cases. Use of the interobserver variance analysis criteria increased complete agreement to 70 percent and reduced partial agreement and complete disagreement to 22 and 8 percent, respectively. Interpretation by multiple observers increases the diagnostic accuracy of the thallium stress test. Averaging of the multiple observer scores and interpretation of the averaged scores using the average criteria appears more useful than interpretation by simple consensus.

625 **Echocardiographic Features of Atrioventricular and Ventriculoatrial Conduction**

MASAHITO NAITO, LEONARD S. DREIFUS, T. JOSEPH MARDELLI, CHIN C. CHEN, DANIEL DAVID, ERIC L. MICHELSON, VAL MARCY and JOEL MORGANROTH

Simultaneous hemodynamic and M mode and two dimensional echocardiographic correlates of changes in cardiac performance resulting from changes in atrioventricular (A-V) conduction patterns. By scanning the A-V interval from +100 to −100 ms in the presence of A-V and V-A sequential packing, these investigators observed progressive decreases in systolic blood pressure, cardiac output and left ventricular size together with increases in left atrial sizes. The findings suggest that echocardiography can provide insight into the mechanisms responsible for the hemodynamic disorders that result from various patterns of A-V conduction or that occur during supraventricular arrhythmias.



PEDIATRIC CARDIOLOGY

635 **Long-Term Evaluation (12 to 22 Years) of Open Heart Surgery for Tetralogy of Fallot**

VALENTIN FUSTER, DWIGHT C. McGOON, MARGARET A. KENNEDY, DONALD G. RITTER and JOHN W. KIRKLIN

This 12 to 22 year long-term evaluation of 396 hospital survivors of 475 patients who underwent repair of tetralogy of Fallot shows an excellent late clinical result in 87 percent. A less than excellent result in the remaining 13 percent was caused by late mortality in 7 percent, need for reoperation in 4 percent and the development of symptoms in 2 percent. Most late deaths and complications appeared within 2 years of operation, and accelerating deterioration in late results did not occur as the follow-up period extended beyond 2 years. Late mortality and reoperation were the two major reasons for the decrease in excellent results during the first 2 postoperative years. Right ventricular outflow abnormalities were the cause of death in seven patients (1.5 percent). Fourteen of the 19 patients required reoperation because of a residual or recurrent ventricular septal defect.

continued on page A30

New evidence is in:

Treatment of mild hypertension can save lives

Even among patients with DBP in the low 90s, systematic therapy significantly reduced mortality:

- Of nearly 11,000 hypertensives identified by the Hypertension Detection and Follow-up Program, slightly more than 70% had mild hypertension (DBP 90-104 mm. Hg).[1]
- Half were given systematic and aggressive care in HDFP centers; half were referred to customary sources of medical care.
- After 5 years, HDFP found that effective treatment of mild hypertension may reduce premature deaths by 20%.[1]
- As part of HDFP's systematic treatment and follow-up program, the primary step-1 agent was chlorthalidone: Hygroton®.[2]

The primary agent used by the HDFP in an effective low dose

Hygroton® 25 mg. one a day
(chlorthalidone USP)

Because there's nothing mild about mild hypertension

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs. **Warnings:** Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn. **Usual Dose:** One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored), 50 mg. (aqua) in bottles of 100, 1000 and 5000; 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips).

Looking to Daig

With its complete line of Pacing Leads, Accessories and, now *PACEMAKERS*

Daig Corporation...the world leader in pacing lead products, now brings a new name to Medcor, Inc. — DAIG/MEDCOR. Separately, both companies have enjoyed the prestige within the medical industry as manufacturers of reliable, well-engineered products of the highest quality.

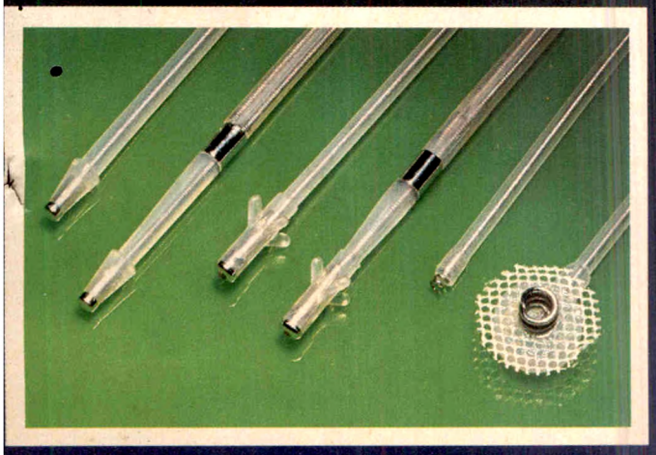
Together, DAIG/MEDCOR supports this reputation by renewing its commitment to provide leadership and uphold its history as an industry innovator in pacing technology.

And...DAIG CORPORATION, will continue its commitment to the development and improvement of cardiac pacing leads and accessories for the world pacemaker market.

Daig/Medcor Lithicron II 400 Series Demand Pulse Generators. Our proven circuitry and reliable lithium power source are backed by eight years of clinical history, resulting in a thin, lightweight, and long-lasting pacemaker. In both unipolar and bipolar configurations, this Lithicron II Series includes our new Collet Connector designed to improve lead holding power while eliminating the possibility of terminal pin distortion.

Lithicron 500 Series Programmable Pulse Generators. Affords total pacing versatility in an easy-to-program format. Real-time telemetry, electronically coded programming, and state-of-the-art hybrid circuitry provide a simple, safe and reliable pacing system.

ALL DAIG/MEDCOR Pulse Generators are backed by a Lifetime Replacement Credit Agreement.



Daig/Medcor Transtelephonic Follow-Up Receiver and Transmitters. Provides a fast, accurate evaluation of your patient's condition anywhere in the world.

Daig/Medcor Pacemaker Programmer. A lightweight, easy-to-use unit displaying real-time telemetry reading of pacer rate, pulse width, and instant confirmation that the pacer has responded to commands.

for the answers.

DAIG CORPORATION'S full line of permanent and temporary pacing leads and accessories has proven superior in clinical tests and is compatible with the majority of today's unipolar and bipolar pulse generators.

Endocardial Screw-In-Lead. Screwed into the right ventricle, or atrium, offering a much wider choice of location sites than other leads.

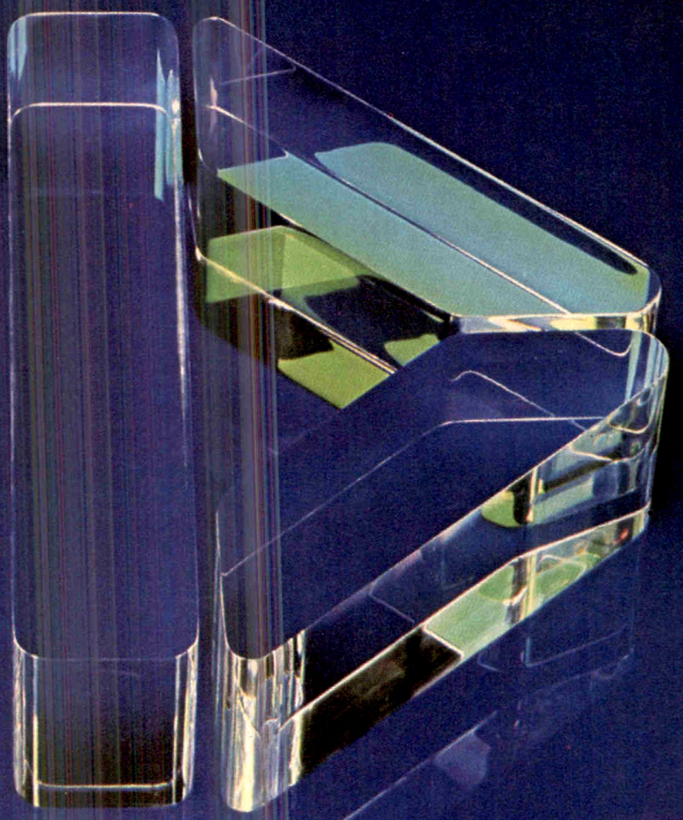
Tined and Wedge-Tip Endocardial Leads. Provides secure ventricular pacing lead placement. The platinum/iridium ring-tip electrode ensures low pacing thresholds and pacemaker longevity.

Myocardial Sutureless Leads. Our newly improved Cam-Loc™ Introducer maximizes patient safety and ease of handling.

Temporary Pacing Leads. With a unique fixed bifurcation and cannula storage system ensuring reliability and efficiency.

Littleford/Spector Introducer. For rapid introduction of a wide variety of pacing leads and catheters.

DAIG CORPORATION and DAIG/MEDCOR are two companies working together to provide an innovative change of pace.



An Innovative Change of Pace

643 **Cardiac Malformations in the Velocardiofacial Syndrome**

DENNISON YOUNG, ROBERT J. SHPRINTZEN and ROSALIE B. GOLDBERG

The findings of velopharyngeal insufficiency, a submucous or overt cleft of the secondary palate, similar facies, learning disabilities and congenital cardiovascular anomalies whose occurrence as single or combined lesions exceeds the expected incidence in children with congenital heart disease constitute the newly designated velocardiofacial syndrome. Observations in 23 patients with this syndrome and their families indicate an unusual conformity of cardiac involvement and suggest the possibility of autosomal dominant or X chromosome-linked dominant transmission in some. Etiologic heterogeneity cannot be ruled out and the possible teratogenic effects of progestional agents given during the early first trimester of pregnancy or of exposure to anesthetic gases during pregnancy are possible but unproved.

EPIDEMIOLOGY

649 **Prevalence of Coronary Heart Disease in the Framingham Offspring Study: Role of Lipoprotein Cholesterols**

PETER W. WILSON, ROBERT J. GARRISON, WILLIAM P. CASTELLI, MANNING FEINLEIB, PATRICIA M. McNAMARA and WILLIAM B. KANNEL

In 43 of the 1,312 men aged 35 to 54 years in the Framingham Offspring Study with clinically recognized coronary heart disease at the initial examination the prevalence of coronary heart disease was strongly associated with age, smoking, high density lipoprotein (HDL), low density lipoprotein (LDL) and total cholesterol using univariate analyses. After multivariate analysis of the data, age, smoking, HDL and LDL cholesterol retained their significant association with coronary heart disease. Both HDL and LDL cholesterol are strongly and independently associated with the prevalence of coronary heart disease; the level of very low density lipoprotein cholesterol makes no statistically significant independent contribution. The total cholesterol/HDL ratio offers the clinician a useful index to associate lipid values with coronary disease.

REPORTS ON THERAPY

655 **Vagal Techniques for Termination of Paroxysmal Supraventricular Tachycardia**

MENASHE B. WAXMAN, ROBERT W. WALD, ARJUN D. SHARMA, FELIX HUERTA and DOUGLAS A. CAMERON

In 68 consecutive patients with paroxysmal supraventricular tachycardia 57 episodes were terminated with carotid sinus pressure alone or after pretreatment with edrophonium, 5 episodes with the Valsalva maneuvers and 6 with phenylephrine. Phenylephrine evoked the greatest increase in vagal tone; the Valsalva maneuver was more potent than carotid sinus pressure. These results confirm that maneuvers that reflexly increase vagal tone can rapidly, safely and consistently terminate paroxysmal supraventricular tachycardia. Apart from drugs that specifically reduce sympathetic tone or enhance vagal tone, reassurance, sedation and the recumbent position may exert similar effects and facilitate termination of tachycardia. Oral therapy with antisympathetic drugs like propranolol, or enhancement of vagal tone by digitalis, will increase the success and ease of termination of the arrhythmia.

665 **Effect of Drugs in the Wolff-Parkinson-White Syndrome. Importance of Initial Length of Effective Refractory Period of the Accessory Pathway**

HEIN J. J. WELLENS, FRITS W. BÄR, WILLEM R. M. DASSEN, PEDRO BRUGADA, EDGARD J. VANAGT and JERÓNIMO FARRÉ

These electrophysiologic observations in 59 patients with the Wolff-Parkinson-White syndrome indicate the importance of the initial value of the effective refractory period of the accessory pathway in determining the effect

QUICK QUIZ

Fig. 1

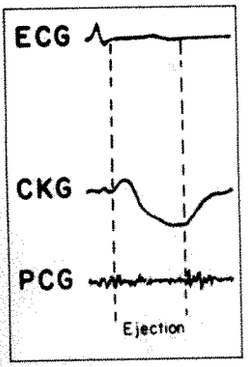

Fig. 2

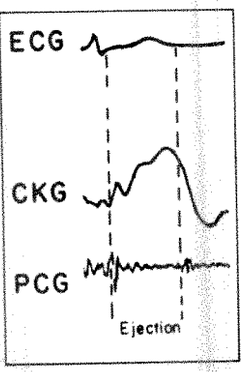

Fig. 3

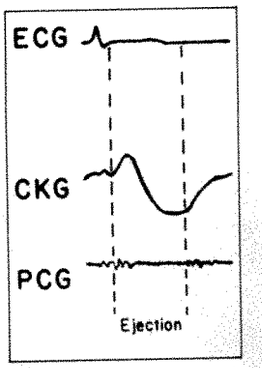

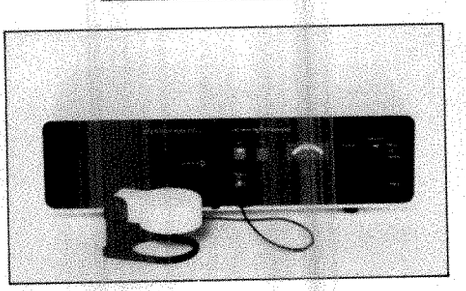

Fig. 4

I. Figure 1 is a pre-stress CKG™ (Cardiokymograph) tracing of the left ventricle (V3 position), it demonstrates:*

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

II. Figure 2 is a two minute post-stress CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

III. Figure 3 is a thirty minute post-stress resting CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

IV. Figures 1, 2 and 3, taken together, demonstrate:

- ☐ A. stress induced ventricular wall motion abnormalities consistent with ischemia
- ☐ B. normal ventricular wall motion

V. According to recently published[1] data, the CKG (Cardiokymograph) stress test is:

- ☐ A. 98% sensitive—98% specific
- ☐ B. 59% sensitive—69% specific
- ☐ C. 74% sensitive—95% specific
- ☐ D. 40% sensitive—60% specific

VI. Figure 4 is a photograph of:

- ☐ A. CKG/700 (Cardiokymograph)
- ☐ B. a noninvasive device that provides an analog representation of wall motion
- ☐ C. a low cost, simple device to be used in conjunction with stress testing to enhance diagnostic accuracy
- ☐ D. all of the above

QUICK QUIZ—ANSWERS

I. A. normal systolic inward motion **II.** C. holosystolic outward motion **III.** A. normal systolic inward motion **IV.** A. stress induced ventricular wall motion abnormalities consistent with ischemia **V.** C. 74% sensitive – 95% specific **VI.** D. all of the above

Dobutrex®
Dobutamine HCl

For Short-Term
Inotropic Support in Patients with
Low-Output Cardiac Failure

See following page for summary of prescribing information.

Selectively Increases
Myocardial Contractility
with Consistent
Hemodynamic Improvements

Dobutrex®
Dobutamine HCl

For I.V. Injection
250 mg* in 20-ml-size vials
* Equivalent to dobutamine

Brief Summary
Consult the package literature for prescribing information.

Indications and Usage: Dobutrex® (dobutamine hydrochloride, Lilly) is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to instituting therapy with Dobutrex.

Contraindication: Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

Precautions: 1. During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex® (dobutamine hydrochloride, Lilly) for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex® (dobutamine hydrochloride, Lilly) is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add an additional 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstituted time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250, 500, and 1000 mcg/ml

Drug Delivery Rate (mcg/kg/min)	Infusion Delivery Rate 250 mcg/ml* (ml/kg/min)	500 mcg/ml† (ml/kg/min)	1000 mcg/ml‡ (ml/kg/min)
2.5	0.01	0.005	0.0025
5	0.02	0.01	0.005
7.5	0.03	0.015	0.0075
10	0.04	0.02	0.01
12.5	0.05	0.025	0.0125
15	0.06	0.03	0.015

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

PRE-INFUSION
ANGIOGRAPH

Abbokinase® makes the difference

Urokinase for Injection

2 HOUR
POST-INFUSION
ANGIOGRAPH

- Abbokinase is not a foreign protein
- Abbokinase is non-antigenic
- Induced antibody formation is not seen in intradermal tests
- Since patient is not sensitized by Abbokinase, therapy can be repeated whenever necessary
- Urokinase neutralizing antibodies are not formed so resistance is not a factor
- Course of therapy is 12 hours and no dosage adjustment is necessary

Abbokinase®

Urokinase for Injection

250,000 I.U. per vial

The direct action thrombolytic agent for the management of acute massive pulmonary embolism

Abbokinase is stocked at strategically located hospitals throughout the country. For the name of the hospital nearest to you, please write Abbott Laboratories, Dept. 517, North Chicago, Illinois 60064.

Please see following page for Brief Summary.

0063343

ABBOTT

Abbokinase®
Urokinase for Injection

Brief Summary

ABBOTT

0063343

ABBOKINASE (urokinase for injection) should only be used by physicians with wide experience in the management of thrombotic disease in hospitals where the recommended clinical and laboratory monitoring (see WARNINGS, PRECAUTIONS and DOSAGE AND ADMINISTRATION) can be performed.

When considering treatment with urokinase, the physician should carefully assess the overall clinical status and history of the patient. The hemostatic capability of the patient is more profoundly altered and bleeding more frequent with urokinase therapy than with heparin or oral coumarin anticoagulant therapy. When bleeding occurs it is also more severe and more difficult to manage. The potential risk of serious hemorrhage relative to such factors as age, physical condition, and underlying bleeding tendency of the patient (as described under WARNINGS and PRECAUTIONS) should be weighed against the potential benefits of treating the patient with urokinase.

INDICATIONS

Pulmonary Embolism

ABBOKINASE (urokinase for injection) is indicated in adults:

for the lysis of acute massive pulmonary emboli, defined as obstruction or significant filling defects involving two or more lobar pulmonary arteries or an equivalent amount of emboli in other vessels.[8]

for the lysis of pulmonary emboli accompanied by unstable hemodynamics, i.e., failure to maintain blood pressure without supportive measures.

The diagnosis should be confirmed by objective means, preferably pulmonary arteriography.

Urokinase treatment should be instituted as soon as possible after onset of pulmonary embolism, and no later than five days after onset. Under these circumstances, angiographic and hemodynamic measurements demonstrate a more rapid improvement during the first 24 hours of therapy than with heparin therapy (Table I).[7-9] However, it has not been established that treatment with urokinase decreases morbidity or mortality, when compared to heparin therapy alone.

TABLE I

	UPET*		USPET**	
	Heparin	12-Hour Urokinase	12-Hour Urokinase	24-Hour Urokinase
Change in angiographic severity score based on 4-point system	0.54	1.78	1.66	1.76
Decrease in relative percentage perfusion defect on lung scans	8.3	24.1	20	29.2
Change in pulmonary artery pressure (mm Hg)	−1.1	−6.2	−7.28	−7.53
Change in cardiac index (l/min/m²)	−0.05	+0.02	+0.06	+0.30

*Urokinase pulmonary embolism trial.
**Urokinase-streptokinase pulmonary embolism trial.

Evaluations were obtained between 18 and 30 hours after the start of therapy. After several days, there were no differences between the results in the heparin treated patients and those receiving urokinase.

CONTRAINDICATIONS — Because thrombolytic therapy increases the risk of bleeding, urokinase is contraindicated in the following situations:

1. Surgery within ten days. Liver or kidney biopsy, lumbar puncture, thoracentesis or paracentesis, extensive or multiple cutdowns should be considered surgical procedures.
2. Intraarterial diagnostic procedure within ten days.
3. Ulcerative wound.
4. Recent trauma with possibility of internal injuries.
5. Visceral or intracranial malignancy.
6. Pregnancy and the first ten days of the post-partum period.
7. Ulcerative colitis, diverticulitis or an actively bleeding lesion (or one with a significant potential for bleeding) of the gastrointestinal or genitourinary tract.
8. Severe hypertension.
9. Acute or chronic hepatic or renal insufficiency.
10. Uncontrolled hypocoagulable state, including one that may be caused by a coagulation factor deficiency, thrombocytopenia, spontaneous fibrinolysis, or another purpuric or hemorrhagic disorder.
11. Chronic lung disease with cavitation, e.g., tuberculosis.
12. Subacute bacterial endocarditis or rheumatic valvular disease.
13. Recent cerebral embolism, thrombosis or hemorrhage. Treatment with urokinase is contraindicated for at least two months after cerebral embolism, thrombosis or hemorrhage because patients with cerebral infarction remain at risk of bleeding into the infarcted tissue.
14. Any other condition in which bleeding might constitute a significant hazard or be particularly difficult to manage because of its location.

The conditions listed above should not be regarded as absolute contraindications. Rather, the risk of hemorrhage must be weighed carefully against the anticipated benefits of urokinase therapy in an individual patient and the benefits and risks associated with the use of urokinase should be compared to the benefits and risks associated with other forms of therapy.

WARNINGS

Bleeding

Activation of the fibrinolytic system with urokinase results in a more profound alteration of the hemostatic status of the patient than does anticoagulant therapy with heparin or coumarin agents. The aim of urokinase therapy is the production of sufficient amounts of plasmin for the lysis of intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example, at sites of needle punctures, are also destined for lysis, and bleeding from such sites may occur. The possibility of bruising or hematoma formation, especially with intramuscular injections, is high during thrombolytic therapy. Unnecessary handling of the patient should be avoided. Strict attention should be given to this section and the CONTRAINDICATIONS section in order to minimize the risk of bleeding.

Because of the high risk of hematoma formation, intramuscular injections must be avoided during urokinase therapy, as with heparin therapy. Bleeding at sites of recent invasive procedures may occur. Hence, arterial invasive procedures must also be avoided before and during treatment with urokinase. Should an arterial puncture be ***absolutely*** necessary, the femoral artery must be avoided and the radial or brachial artery used. It should be done carefully by a physician experienced in such a procedure. Pressure should be applied for at least 15 minutes, a pressure dressing applied, and the puncture site checked frequently for evidence of bleeding. Also, venipunctures should be performed as carefully and infrequently as possible. If the bleeding from an invasive site is not serious, treatment may be continued with appropriate clinical observation. Local measures, i.e., pressure, should be initiated immediately.

Spontaneous bleeding from internal sites (not accessible for pressure application) may also occur. The risk of spontaneous bleeding is greater in patients with pre-existing hemostatic defects, e.g., patients with histories suggestive of prior bleeding problems, with or without demonstrable abnormalities in platelet count, prothrombin time, partial thromboplastin time, or bleeding time. Such patients should be assessed carefully before initiating treatment with urokinase.

In addition to its fibrinolytic action, plasmin also degrades fibrinogen, Factor V, Factor VIII, and other proteins. The products of plasmin degradation of fibrinogen and fibrin (FDP/fdp) possess an anticoagulant effect. Bleeding may be difficult to control because of this anticoagulant effect.

Should serious spontaneous bleeding occur, the infusion of urokinase should be terminated immediately, and treatment instituted as described under ADVERSE REACTIONS.

Predisposition to Cerebral Embolism

Treatment with urokinase of patients with atrial fibrillation or other conditions in which there is possible risk of cerebral embolism may be hazardous because of the risk of bleeding into the infarcted area.

Use of Anticoagulants

Concurrent use of anticoagulants with urokinase is not recommended and may be hazardous. Before starting urokinase in patients being treated with heparin, the effects of heparin should be allowed to diminish with time. As a general rule, a thrombin time of ***less than twice*** the normal control value is adequate for starting urokinase infusions safely. Similarly, heparin should not be started following urokinase therapy until the thrombin time has returned to ***less than twice*** the normal control value.

Rethrombosis has been observed after termination of urokinase treatment. In order to minimize this risk, the use of intravenous heparin followed by oral anticoagulant therapy is considered a necessary adjunct following urokinase therapy (see DOSAGE AND ADMINISTRATION).

Use in Pregnancy

See CONTRAINDICATIONS.

Use in Children

Safety and effectiveness of urokinase therapy in children have not been established; therefore, treatment of such patients is not recommended.

PRECAUTIONS

Drug Interactions

Concurrent use of drugs that may alter platelet function, e.g., aspirin, indomethacin, and phenylbutazone, should be avoided. The interaction of ABBOKINASE (urokinase for injection) with other drugs has not been studied.

Laboratory Monitoring

In patients who have received heparin, the thrombin time should be measured prior to starting urokinase. (See WARNINGS.) Similarly, the thrombin time should be monitored following urokinase therapy prior to instituting heparin. (See DOSAGE AND ADMINISTRATION.) During urokinase administration, the levels of fibrinogen, plasminogen, Factor V, and Factor VIII are usually substantially diminished. Concomitantly, the level of fibrin(ogen) degradation products (FDP/fdp) is increased. The combination of reduced fibrinogen and increased FDP/fdp results in a prolongation of the thrombin time. While changes in any of these parameters may serve as confirmation of the existence of a lytic state, no adjustment of dosage should be made on the basis of these test results.

ADVERSE REACTIONS

Incidence and Management

Strict observance of the contraindications, warnings, and precautions to the use of urokinase is essential to minimize the incidence and severity of adverse effects.

BLEEDING

Incidence

Where thrombolytic agents (streptokinase and urokinase) were used in the same controlled clinical trial, severe bleeding (patients receiving a transfusion of greater than two units of blood) was seen in 4 and 6%, respectively. Several fatalities due to cerebral hemorrhage have occurred during urokinase therapy.

Less severe spontaneous bleeding has been observed during urokinase treatment at approximately twice the frequency as that occurring during heparin therapy. Oozing of blood from sites of percutaneous trauma is frequent; hence, all invasive procedures, especially arterial punctures and intramuscular injections must be avoided and intravenous punctures kept to a minimum before and during treatment with urokinase.

A moderate decrease in hematocrit not accompanied by clinically detectable bleeding occurred in approximately one out of five patients treated with urokinase.

Management of Severe Bleeding

In case of serious bleeding, urokinase therapy must be discontinued. If blood loss has been large, packed red cells are indicated. Plasma volume expanders (other than Dextran) are indicated to replace blood volume deficit. If only whole blood is available, it may also be used. Although the use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for urokinase has not been documented, it may be considered if the hemorrhage is unresponsive to blood replacement. (See WARNINGS.)

ALLERGIC REACTIONS

Although urokinase is a protein of human origin, and *in vitro* tests with the drug, as well as intradermal test in humans, gave no evidence of induced antibody formation, the possibility of serious allergic reactions (including anaphylaxis) occurring with its use cannot be excluded. Relatively mild allergic reactions, e.g., bronchospasm and skin rash, were reported rarely.

FEVER

Febrile episodes occurred in approximately two to three out of 100 patients. A cause and effect relationship has not been established. Symptomatic treatment is usually sufficient to alleviate discomfort. The use of acetaminophen rather than aspirin is recommended.

DOSAGE AND ADMINISTRATION

Dosing

ABBOKINASE IS INTENDED FOR INTRAVENOUS INFUSION ONLY.

A priming dose of 2,000 I.U./lb (4,400 I.U./kg) of ABBOKINASE is given as the Abbokinase-Normal Saline admixture over a period of ten minutes. This is followed by a continuous infusion of 2,000 I.U./lb/hr (4,400 I.U./kg/hr) of ABBOKINASE (given as the Abbokinase-Normal Saline admixture) for 12 hours. The total volume of fluid administered should not exceed 200 ml.

Administer ABBOKINASE (urokinase for injection) by means of a constant infusion pump that is capable of delivering a total volume of 195 ml.

Anticoagulation After Terminating Urokinase Treatment

At the end of urokinase therapy, treatment with heparin by continuous intravenous infusion is recommended. Heparin treatment should not begin until the thrombin time has decreased to ***less than twice*** the normal control value. See manufacturer's prescribing information for proper use of heparin.

of subsequent drug administration on the duration of this period. In the anterograde direction the magnitude of increase in the length of the effective refractory period of the accessory pathway after administration of procainamide, quinidine, ajmaline and amiodarone was related to its initial length. Only modest lengthening of this period could be accomplished in patients with an initially short period. Only amiodarone consistently caused moderate prolongation of this period. Patients with a short effective refractory period of the accessory pathway (at risk of high ventricular rates if atrial fibrillation supervenes and most in need of lengthening of this period) are least likely to benefit from commercially available drugs. Amiodarone might best protect such patients against life-threatening ventricular rates when atrial fibrillation supervenes.

670 Pharmacokinetic-Hemodynamic Studies of Nitroglycerin Ointment in Congestive Heart Failure

PAUL W. ARMSTRONG, JOYCE A. ARMSTRONG and GERALD S. MARKS with the technical assistance of JAMES McKINVEN and SUSAN SLAUGHTER

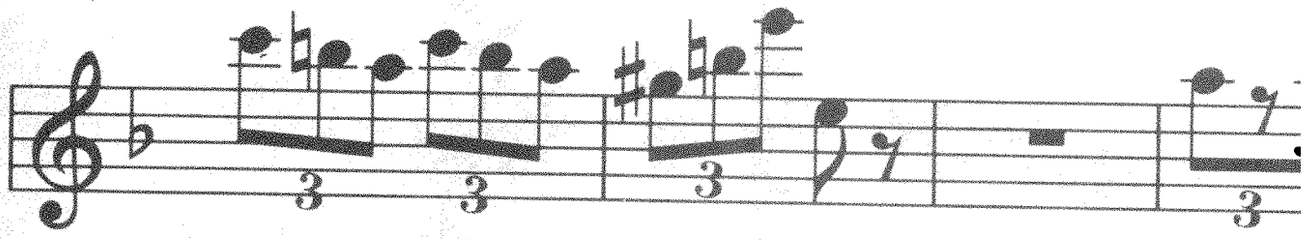
Documenting the bioavailability of nitroglycerin delivered percutaneously to patients with congestive heart failure, this study in 14 patients demonstrated a good correlation between the dose of nitroglycerin ointment and nitroglycerin bioavailability. Nitroglycerin ointment provided therapeutic levels of nitroglycerin associated with prompt substantial hemodynamic benefit as demonstrated by decreased pulmonary capillary wedge pressure and right atrial pressure 30 minutes after application in selected patients with heart failure. There was a greater decrease in the pulmonary capillary wedge pressure in the small dose group (31 percent) compared with the large dose group. A subset of patients was identified who had minimal response to nitroglycerin despite plasma concentrations of 9 ng/ml. Such lack of response probably represents target organ resistance in peripheral arterioles and veins, can be anticipated by prior intravenous nitroglycerin infusion and is best detected by hemodynamic monitoring.

677 Simultaneous Anterograde Fast-Slow Atrioventricular Nodal Pathway Conduction After Procainamide

JOSEPH ANTHONY C. GOMES, PRITPAL S. KANG, GEORGE KELEN, RAHMAN KHAN and NABIL EL-SHERIF

Electrophysiologic recordings in three patients with paroxysmal supraventricular tachycardia before and after the intravenous infusion of 500 mg of procainamide revealed that this drug altered conduction and refractoriness of the anterograde fast and slow pathways so that simultaneous conduction could occur during atrial pacing, producing a double ventricular response and a slow-fast echo or tachycardia, or both. The electrophysiologic data in all three indicated that the region of the atrioventricular (A-V) node was the site of reentry. The differential effects of procainamide on anterograde fast and retrograde fast pathways suggest that these are two functional A-V nodal fast pathways, one for anterograde and the other for retrograde conduction. The retrograde fast pathway is physiologically and perhaps anatomically distinct from the anterograde fast pathway. The drug response of the retrograde fast pathway resembles that of Purkinje muscle, whereas the response of the anterograde fast pathway resembles that of the A-V node.

REVIEWS



685 Systemic Arterial Hypertension Associated With Cardiac Surgery

FAWZY G. ESTAFANOUS and ROBERT C. TARAZI

Serious hypertension can occur with any type of cardiac surgery. It has been reported to complicate the course of 30 to 50 percent of patients subjected to coronary bypass surgery. The hypertensions have different causes and mechanisms. A classification such as the one proposed in this review, based on well defined clinical events such as timing in relation to surgery, allows an acceptable definition of hypertension that permits comparison of reports from different observers. Careful appraisal of antihypertensive therapy is an essential step in preparation for surgery. The definition of the mechanisms underlying the increase in arterial pressure at different stages of surgery or in the postoperative period facilitates a rational choice of therapy. Prophylactic, general and specific antihypertensive measures to control the more common type of hypertension complicating cardiac surgery are outlined.

continued on page A44

An impressive therapeutic performance...

In tune with contemporary antihypertensive thinking

Today antihypertensive therapy has gone beyond the empirical addition of one drug to another. Today's clinician looks for agents that coordinate their action for smoother, more effective control.

A prime example is increasing use of the Apresoline/beta-blocker/diuretic regimen in moderate-to-severe hypertension. Beta blockers, though effective and generally well tolerated, do not lower the high peripheral resistance found in virtually all long-standing hypertension. As a vasodilator, Apresoline deals directly with the problem. It can decrease total peripheral resistance by more than 60%.

Beta blockers, on the other hand, specifically reduce cardiac output, which tends to rise through reflex action with Apresoline therapy, while diuretics counteract the retention of sodium and extracellular fluid.

Harmonizing with the antihypertensive life-style

The Apresoline/beta-blocker/diuretic regimen is relatively free of serious side-effect problems that interfere with daily living.

As the only therapeutic action of Apresoline is its direct arteriolar vasodilator effect, it avoids many distressing side effects. Sexual dysfunction, drowsiness, lethargy, and sedation are virtually unknown. Postural hypotension is rare. These side effects are usually also avoided with a beta blocker.

Accompanying a fall in blood pressure from Apresoline is an increase in cardiac rate and output. Apresoline also maintains or increases renal and cerebral blood flow. As with any antihypertensive agent, use with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.

After a diuretic...

Apresoline® & (hydralazine)

the beta blockers

Apresoline® hydrochloride
(hydralazine hydrochloride USP)

TABLETS

INDICATIONS

Essential hypertension, alone or as an adjunct.

CONTRAINDICATIONS

Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.

WARNINGS

Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary.

Complete blood counts, L.E. cell preparations, and antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is symptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms.

A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.

Use MAO inhibitors with caution in patients receiving hydralazine.

When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure. Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.

Usage in Pregnancy

Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and malformations of facial and cranial bones. Although clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.

PRECAUTIONS

Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore, be used with caution in patients with suspected coronary artery disease.

The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine. Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.

In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improved renal function has been noted where control values were below normal prior to Apresoline administration. However, as with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage.

Peripheral neuritis, evidenced by paresthesias, numbness, and tingling, has been observed. Published evidence suggests an antipyridoxine effect and the addition of pyridoxine to the regimen if symptoms develop.

Blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura, have been reported. If such abnormalities develop, discontinue therapy.

Periodic blood counts are advised during prolonged therapy.

The Apresoline tablets (10 and 100 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Adverse reactions with Apresoline are usually reversible when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.

Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.

Less frequent: Nasal congestion; flushing; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.

DOSAGE AND ADMINISTRATION

Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.

The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline.

In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

CASE REPORTS

695 **Selection of Angina-Free Patients With Severe Left Ventricular Dysfunction for Myocardial Revascularization**

CARY W. AKINS, GERALD M. POHOST, ROMAN W. DeSANCTIS and PETER C. BLOCK

Stress thallium-201 myocardial imaging proved useful in two angina-free patients with severe congestive heart failure to identify clinically silent areas of ischemic myocardium and to distinguish between scar and reversibly ischemic myocardium as a cause for akinesia of left ventricular wall segments. Myocardial revascularization improved the patients' clinical state and findings in the postoperative nuclear scans. Because the sensitivity of angina as a clinical marker of severe coronary artery disease is probably very low, other clinical presentations of coronary artery disease, such as functional mitral insufficiency, atrial and ventricular arrhythmias, congestive heart failure and atypical pain and dyspnea, might be clinically grouped as ischemic equivalents of coronary artery disease.

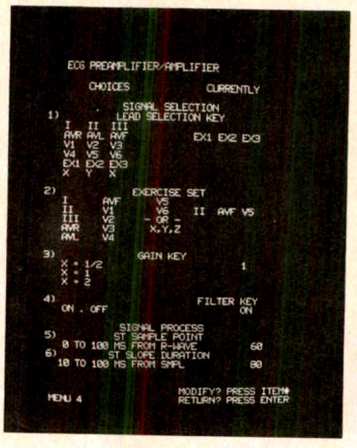
WITH AN IMAGINATION TO MATCH YOUR OWN

Status 1000, The ECG Monitor That Gives You Programmable Control Over Every Aspect Of The Stress Test.

Quinton's Status 1000 is the first ECG stress test system that lets you use your imagination to modify or reprogram at will the various elements of a stress test.

Not just treadmill protocol, but lead selection, ST sample point, recorder speed, patient name, final report content and length, blood pressure prompting, etc. Everything is in your control like it should be.



Use your professional imagination to create and program customized test procedures for pediatric, research, post-M.I., rehab., or out-patient situations.

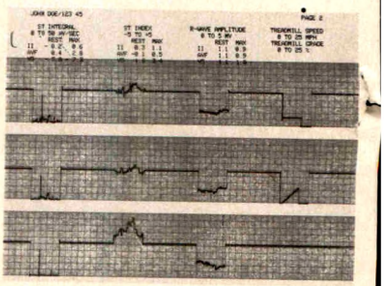
Each physician in your institution can have their own preferred test procedure stored in memory.

With the Status 1000 you and your colleagues can customize test procedures based on the requirements of the patient, not the restrictions of the ECG system.

How The Sophisticated Status 1000 Makes Test Flexibility So Complete And Easy

With The Status 1000, Quinton introduces a new term, the "Stress Test Environment". It consists of 16 test elements. Each element, such

as exercise lead set, or final report content, has parameters which you can establish or modify to suit your needs.



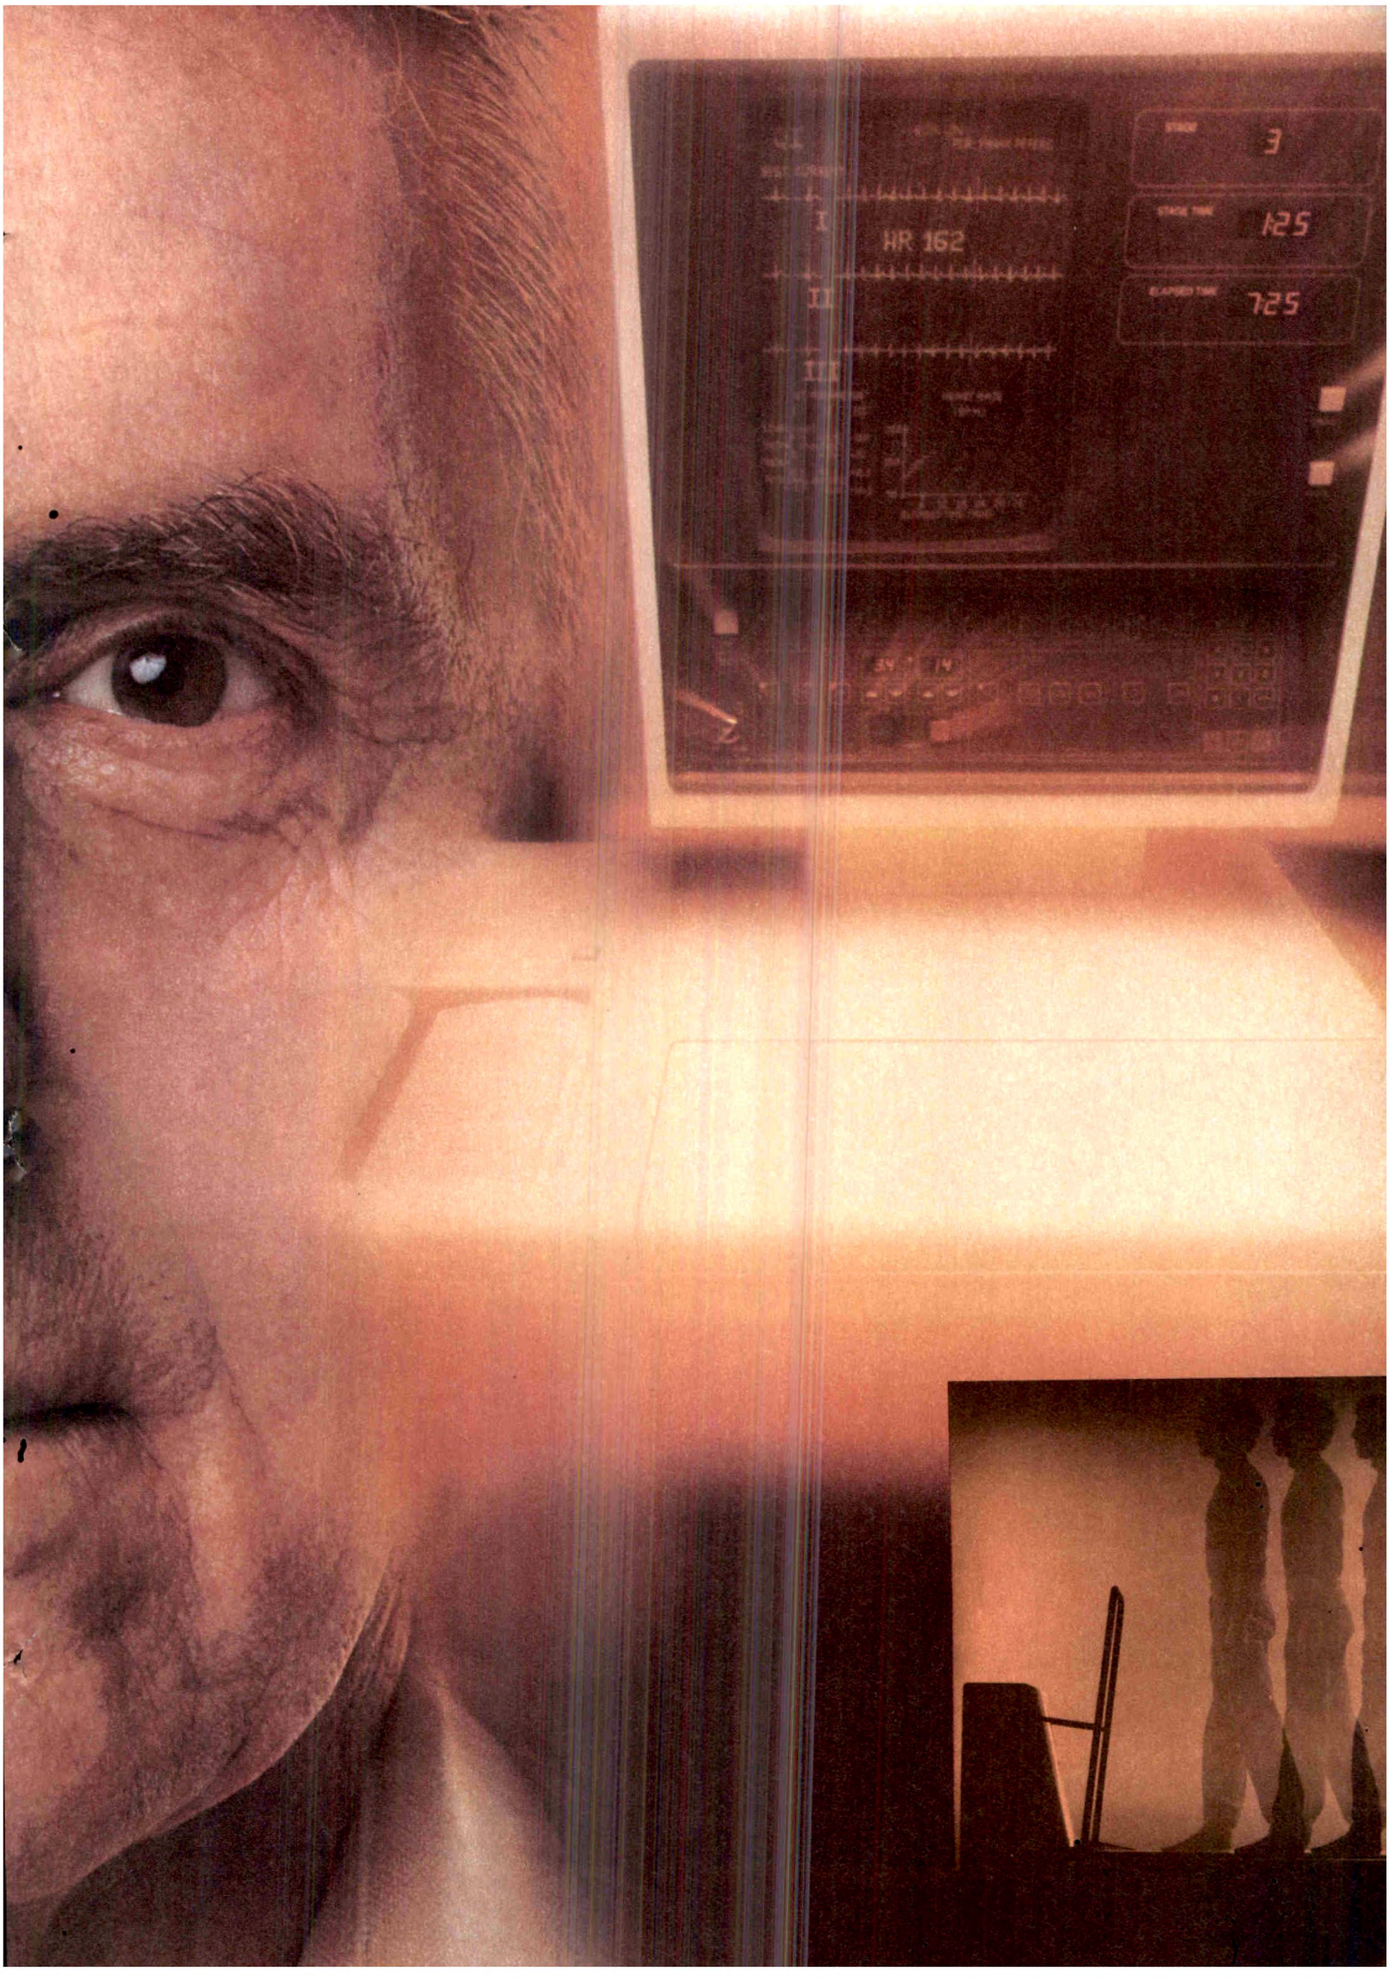
Yet, programming the Status 1000 is as easy as operating a pocket calculator, so special training is not required.

Comprehensive Data, Professionally Presented

In a single glance you see three channels of diagnostic quality ECG, averaged beats (both resting and current), heartrate, computed parameters, trend displays, stage number, stage time and elapsed time.

Plus, any abnormal beat will be instantly highlighted on the screen, then recorded and labeled automatically.

Your control extends to test reports, too. Printouts during the test may include averaged beats, rhythm strips, or full 12-leads. Final reports may include a wide variety of information. And each report is automatically labeled with pertinent data. Good bye work sheet.



Stay Ahead With The Status 1000

Because of the Status 1000's unparalleled flexibility and microprocessor technology its susceptibility to obsolescence is far less than other systems. And that makes it a good investment for you and your institution. Call Quinton toll free at 1-800-426-0538.

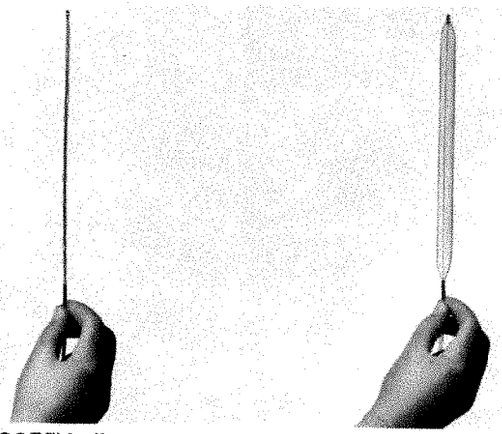
At last, intra-aortic balloon pumping without surgery.

Datascope introduces the PERCOR™ balloon for percutaneous insertion.

For all of its benefits, intra-aortic balloo pumping has had one ever-present shortco ing. The balloon had to be inserted and removed surgically.



The Datascope®PERCOR balloon* puts an end to all that.

This remarkably innovative device is easily and quickly inserted through the skin, using t Seldinger catheterization technique.

The surgical insertion that used to take 20 to minutes is now completed without surgery in approximately 5 minutes. Further, removal is accor plished in minutes without surgery as well.

With this new technique, it is apparent that intra-aortic balloc pumping, when indicated, will be used by more medical specialis in a wider variety of clinical settings for the benefit of increasing numbers of patients. In the oper ing room, the catheterization lab, CCU and emergency room. By t surgeon, the radiologist, the cardiologist.

We would be pleased to send you more information about our revolutionary device and to schedule a filmed demonstration of its use. Call Robert Rewolinski Manager, Cardiac Assist Products, at 201-265-8800 or write him at Datascope Corp., Dept. #5-S, 580 Winters Avenue, Paramus, NJ 07652.

PERCOR™ balloon ready for insertion.

PERCOR™ inflated.

An open letter to our friends in the Medical Community.

We have looked forward, each year, to the Annual Meeting of The American Heart Association, because it is at these prestigious gatherings that we have had an opportunity to show our appreciation for the support the Medical Community has shown to our company and our products. We have done this by hosting entertainment receptions, especially designed for convention attendees. Perhaps you have been our guest.

The reaction we've had has always been favorable, so it came as quite a surprise when we received a notice from the AHA this year that (it) "has ruled that industry sponsored mass entertainment activities are prohibited..." during the convention dates.

Ruled? The AHA has *ruled* that we, and other companies, cannot host functions for our friends in the profession? Well, you can imagine how startled we were to hear *that!*

Help us to understand such a "ruling." Is it reflective of *your* views? Take a moment now to fill out the simple questionnaire below and send it back to us, so that we can know of your feelings on the subject.

We wish to play by the rules, of course. But what should we do when such "rules" infringe upon the rights of a company to say "thank you" to the people we've been priviliged to work with over the year?

We'd like to know what *you* think.

The Human Cardiovascular System
Facts and Concepts

By: J. T. Shepherd and P. M. Vanhoutte

This textbook is designed for use in medical school courses in introductory cardiology and physiology, as well as for more advanced use by those beginning specialty training or others wishing a general review of the basic function of the human cardiovascular system. Beginning with a discussion of the normal functioning of the cardiovascular system, the text logically leads into discussions of common pathological situations and their management.
375 pp., $14.95 (paper), $25.00 (cloth) (1979) ISBN 0-89004-367-1

Pharmacology of Antihypertensive Drugs

Editor: A Scriabine

Each chapter in this volume has been prepared by pharmacologists and other medical specialists who actively participated in the development of antihypertensive drugs and were in many cases the actual discovers and developers of the activity of the drug they describe. For each antihypertensive drug in current use or advanced development, chapters review mechanisms of action, secondary pharmacological properties, and side effects.
472 pp., $37.50 (1980) ISBN 0-89004-329-9

Prostacyclin

Editors: J. R. Vane and S. Bergström

This volume reviews in comprehensive fashion our current understanding of the chemistry, physiology, and pharmacology of prostacyclin and its analogs, and discusses their therapeutic potential. Much of the volume focuses on the interaction between the effects of prostacyclin and thromboxane A_2. The balance between these two members of the prostaglandin family has tremendous significance for the state of health or disease within the cardiovascular system.
472 pp., $43.00 (1979) ISBN 0-89004-330-2

The Aging Heart: Its Function and Response to Stress
(Aging, Vol. 12)

Editor: M. L. Weisfeldt

This volume discusses the pathophysiological changes that occur in the human cardiovascular system as a function of age. Sections focus on the contractile and elastic properties of cardiac muscle, the heart as a single organ within the body, the integration of the components of the cardiovascular system, and its response to pharmacologic agents.
335 pp., $29.50 (1980) ISBN 0-89004-307-8

Mechanisms of Cardiac Morphogenesis and Teratogenesis
(Perspectives in Cardiovascular Research, Vol. 5)

Editor: T. Pexieder

This volume presents a multidisciplinary analysis of the cellular and subcellular mechanisms regulating cardiac morphogenesis and teratogenesis in the embryo. The material is organized into three major areas: organogenesis of the heart, cellular and subcellular mechanisms, and regulatory aspects. Each section includes findings from both human and animal studies, particularly on the rat and chick embryo.
Approximately 525 pp., 251 figures, tentatively $48.00
(October 1980) ISBN 0-89004-460-0

Journal of Cardiovascular Pharmacology

Editors-in-Chief: Leon I. Goldberg and Jan Koch-Weser

This bimonthly journal aims to bring together new information about cardiovascular drugs from research workers and the clinicians who use these drugs in therapy. Its scope covers all old and new pharmacologic agents that directly or indirectly affect the heart and blood vessels and their contents. The journal publishes original or review articles on the creation of such drugs and on their mechanism of action, development and evaluation, therapeutic effectiveness, metabolism, side effects, and interactions.
Personal subscriptions, U.S. $48.00; elsewhere $59.00
Institutional subscriptions, U.S. $58.00; elsewhere $68.00

Prostaglandins and Cardiovascular Disease
(Atherosclerosis Reviews, Vol. 8)

Editor: R. J. Hegyeli

This volume reviews our current understanding of the role of prostaglandins in the normal functioning of the cardiovascular system, in a variety of pathologic conditions, and in medical management of these conditions. Topics include the role of prostaglandins in the control of blood pressure, platelet aggregation, and cyclic AMP levels in heart muscle and arterial walls. The potential use of prostaglandins and their derivatives as pharmacologic agents is also considered, as well as the mechanisms of action of drugs such as antianginal and antihypertensive agents that require the presence of prostaglandins.
Approximately 200 pp., tentatively $25.00 (October 1980)
ISBN 0-89004-516-X

Measurement and Control of Cardiovascular Risk Factors
(Atherosclerosis Reviews, Vol. 7)

Editor: R. J. Hegyeli

This volume focuses on the control of cardiovascular disease by environmental modification. Chapters discuss the epidemiology of coronary artery disease, the major predisposing factors, the role of smoking and diet in its development, drug treatment of primary hyperlipidemias, and the role of vasospasm and other modulatory factors. This volume will be of interest to all those concerned with the development and management of coronary artery disease, including specialists in cardiology and internal medicine and clinical researchers in this field.
340 pp., $34.00 (1980) ISBN 0-89004-396-5

Nutrition, Lipids, and Coronary Heart Disease, A Global View
(Nutrition in Health and Disease, Vol. 1)

Editors: R. Levy, B. Rifkind, B. Dennis, and N. Ernst

"A lucid, well integrated, well documented discussion of the complex relation between diet and coronary-artery disease. Seldom has the topic received such careful scrutiny and balanced, succinct treatment as in this book."– New England Journal of Medicine
"A most unique source to find out important information about diet. . . . The authors and editors deserve our praise for a much-needed and handy source of reference. This book is a ray of sunshine in a dark and dusty area."–JAMA
576 pp., $48.00 (1979) ISBN 0-89004-181-4

CLINICAL STUDIES

Absence of Correlation Between Coronary Arterial Atherosclerosis and Severity or Duration of Diabetes Mellitus of Adult Onset

VINCENT J. VIGORITA, MD
G. WILLIAM MOORE, MD, PhD*
GROVER M. HUTCHINS, MD

Baltimore, Maryland

The relation between the severity and duration of diabetes mellitus and the severity of ischemic heart disease is uncertain. The clinical findings and the findings at autopsy were studied in 185 patients with diabetes mellitus of adult onset who ranged in age from 37 to 91 years and had a clinical diagnosis of diabetes established for a few days to 50 years before death. No statistically significant association was demonstrated either by simple correlation or by multivariate regression analysis between the clinically diagnosed severity or duration of diabetes and either the overall coronary disease, the number of diseased vessels or the number of myocardial infarctions. The presence of other expected correlations in the multivariate analysis suggested that the results of this study were not spurious. However, comparison with 185 age- and sex-matched control patients revealed that *on the average,* diabetic patients have more overall coronary disease ($p < 0.002$), more diffuseness of coronary disease ($p < 0.005$), more coronary collateralization ($p < 0.001$), more vessels involved by atherosclerosis ($p < 0.001$) and more myocardial infarcts ($p < 0.001$). The results suggest that although diabetes mellitus of adult onset is a condition in which the larger coronary arteries are subject to more atherosclerosis than are those in nondiabetic subjects, the progression of the atherosclerotic disease is unrelated to the duration or severity of the diabetes mellitus.

From the Department of Pathology of The Johns Hopkins Medical Institutions, Baltimore, Maryland. This work was supported by Grant P50-HL-17655-06 from The National Institutes of Health, Public Health Service, Department of Health, Education, and Welfare, Bethesda, Maryland. Manuscript received February 4, 1980; revised manuscript received April 21, 1980, accepted April 25, 1980.

* Research fellow of the American Heart Association Maryland Affiliate, Inc., Baltimore, Maryland.

Address for reprints: Grover M. Hutchins, MD, Department of Pathology, The Johns Hopkins Hospital, Baltimore, Maryland 21205.

Although coronary artery disease may not be an inevitable consequence of diabetes mellitus,[1–4] patients with diabetes of adult onset appear to have more coronary artery disease than do control populations not suffering from diabetes.[5–16] Previous studies have indicated that patients with adult onset diabetes have increased atherosclerosis,[8,17–19] myocardial infarction[16,20,21] and morbidity and mortality from cardiovascular disease.[10,22–25] Whereas microvascular changes are the hallmark of renal and retinal tissue in diabetes,[16] it is not known whether cardiac injury results from large vessel coronary disease,[27,28] microangiopathy[29,30] or an interstitial myocardial process.[31–34]

Recent studies using coronary angiography in evaluating patients for surgical correction of atherosclerotic heart disease have led to contro-

versy concerning whether the angiographic findings in diabetic patients with vascular disease are different in type and severity from those of others so evaluated.[28,29,34–41] In addition, most clinical studies have understandably examined only those patients seeking medical help for symptoms related to vascular disease. Therefore, substantial information on asymptomatic diabetic patients or those refusing invasive clinical techniques is lacking, a point of considerable importance when considering the increased incidence of painless myocardial infarction among diabetic patients.[6,42–45]

We reviewed the clinical and pathologic data on 185 consecutive autopsy patients with diabetes of adult onset, and examined their postmortem coronary arteriograms in an effort to see whether correlations existed between the clinically determined severity of diabetes and the extent of coronary artery disease. We also compared the arteriograms of diabetic patients with those of age- and sex-matched nondiabetic patients coming to autopsy during the same period. Our findings indicate that, regardless of the cause of death, diabetic patients as a group have more angiographically determined coronary disease than a control population coming to autopsy. However, neither the clinically evaluated degree of diabetes nor its duration was associated with the extent or severity of angiographically evident coronary artery disease.

Methods

Study patients: One hundred eighty-five patients were included in this study. All had a clinically established diagnosis of diabetes mellitus of adult onset, underwent autopsy at The Johns Hopkins Hospital between 1968 and 1978 and had had a heart study performed with a standard method using coronary arteriography and fixation in distension.[46] The patients ranged in age from 37 to 91 years (average 65); 100 were men (57 white and 43 black) and 85 were women (35 white and 50 black). Hearts studied in this manner comprised 22 percent of patients undergoing autopsy at The Johns Hopkins Hospital during this period, and were, in general, selected on the basis of expectation of cardiac disease irrespective of the presence of diabetes mellitus. The major interest in performing this procedure was the evaluation of ischemic heart disease, so the heart in such patients was usually studied and consequently coronary artery disease was disproportionately represented in the series of injected hearts. The heart was studied in most adult patients with previous cardiac surgery, irrespective of type; in contrast, almost no infants or children were included in the series of cases examined.

Preparation of the heart: Coronary arteries were injected at a pressure of 100 to 150 mm Hg with a barium-pigment-gelatin mass to which formalin had been added. After injection, cannulas were tied into the atria and great vessels, the remaining orifices were ligated and the chambers were distended with 10 percent formalin through the cannulas at 30 to 40 mm water pressure while the heart was suspended in a container of formalin. After overnight fixation, photographs and stereoscopic radiographs were prepared of the fixed distended heart and of the transverse sections into which it was sliced. The coronary arteries were transected at 2 to 3 mm intervals and compared with the radiographic findings. Representative portions of myocardium, including all grossly discernible lesions, and portions of the coronary arteries were taken for histologic examination.

Assessment of severity of diabetes: The medical records of all patients were reviewed to assess the clinical severity of diabetes, including associated cardiovascular, retinal, renal and neurologic disease. The age at which diabetes was first diagnosed, age at death, race and sex were noted. Juvenile diabetic patients (age less than 17 years at the time of diagnosis) were excluded. The duration between the clinical diagnosis of diabetes and death ranged from a few days to 50 years (average 9.5 years). The severity of diabetes was graded as *trivial* in 47 patients, *mild* in 81, *moderate* in 33 and *severe* in 19. Five patients had insufficient clinical data to categorize the severity.

Values for serum glucose, serum creatinine, serum urea nitrogen, serum cholesterol and hematocrit were recorded. Many clinical and autopsy findings were best assessed with a subjective grading system. We used a scale of *none, slight, low moderate, high moderate and severe* for each such feature, and normalized these grades on a scale of 0 to 100 to make the regression coefficients comparable with one another. We assessed the severity of diabetes in each patient on the basis of objective data and the clinicians' impressions as stated in the medical record: *slight* for maintenance of normal serum glucose levels without therapy or with dietary restrictions only; *low moderate* for therapy with oral hypoglycemic agents without manifestations of diabetes-related vascular, retinal, renal or neurologic disease; *high moderate* for oral hypoglycemic therapy with known vascular, retinal, renal or neurologic disease or use of insulin, or both; and *severe* for insulin-dependency with a history of either episodes of acidosis, severe retinopathy or peripheral vascular disease. The type and duration of therapy, including control by diet, oral hypoglycemic agents or insulin, were recorded: *none* for no therapy, *moderate* for continuous or sporadic application of therapy for less than 2 years and *severe* for application of therapy for 2 or more years. The number of episodes of acidosis and coma was recorded.

Retinopathy was graded as *slight* for general constriction of the retinal vessels; *low moderate* for the presence of retinal hemorrhages or microaneurysms, or both; *high moderate* for soft or hard exudates; and *severe* for retinitis proliferans or blindness. Urinalysis performed within 1 month of death was graded as *none* for detectable glucose, protein or ketone bodies in the urine; *slight* for recurrent low grade glycosuria; *low moderate* for recurrent low grade proteinuria (at least 1+ protein by standard reagent strip) with or without glycosuria; *high moderate* for recurrent high proteinuria with glycosuria; and *severe* for recurrent proteinuria or glycosuria with detection of ketones. Renal failure was graded as *none* for no clinically discernible disease; *slight* for recurrent proteinuria, abnormally elevated serum creatinine and abnormally elevated blood urea nitrogen; *low moderate* for episodes of renal failure; *high moderate* for chronic renal failure; and *severe* for renal failure requiring dialysis.

Grading of hypertension and cardiovascular disease: Hypertension was graded as *absent* for normotensive subjects; slight for arterial pressure less than 150/95 mm Hg; *low moderate* for arterial pressure greater than 150/95 mm Hg with a history of antihypertensive therapy; *high moderate* for arterial pressure greater than 160/110 mm Hg with a history of antihypertensive therapy; and *severe* for arterial pressure greater than 200/140 mm Hg. The number of cerebral vascular accidents was recorded.

Peripheral vascular disease in a lower limb was graded as *slight* for trophic skin ulceration, *low moderate* for intermittent claudication, *high moderate* for toe amputation and

severe for more proximal amputations or gangrene. Peripheral neuropathy was graded to reflect the extent of primarily sensory impairment in limbs, including absent ankle jerks, loss of vibration sense and numbness and tingling. Amputations were graded in terms of the amount of limb lost.

Angina, if present, was graded as *slight* for at least one recorded complaint of chest pain before the final hospital admission, *moderate* for repeated episodes and *severe* for incapacitation. Congestive heart failure was graded as *absent* for patients without failure, *slight* if well controlled with or without medication, *moderate* for recurrent failure requiring medication and hospitalization and *severe* for refractory failure. In addition, electrocardiographic abnormalities by history were graded as *absent* for no abnormalities in the final or previous hospital admission, *moderate* for such nonspecific changes as ST-T wave changes and *severe* for at least one episode of abnormal readings in a recent admission. The patient's obesity, number of pack-years of cigarette smoking and family history of diabetes were recorded.

Autopsy data: We collected autopsy data including weight of the heart, liver and kidneys, and the degree of atherosclerosis involving the coronary, pulmonary, cerebral and systemic circulations. The thickness of the abdominal panniculus was taken as a measure of obesity. Vascular disease was graded as *none* for no intimal disease, *mild* for an occasional atherosclerotic plaque, *moderate* for multiple plaques and *severe* for atherosclerosis with partial or total arterial occlusions. The number of myocardial infarcts ascertained during postmortem study was recorded.

Grading of coronary artery disease: The postmortem arteriograms were evaluated for the number of the three major vessels (left anterior descending, left circumflex and right coronary arteries) with significant (greater than 75 percent) reduction of the luminal area. The overall severity of atherosclerosis demonstrated angiographically, confirmed by serial transections at 2 to 3 mm intervals of the epicardial coronary arteries, was graded as *none* for no discernible disease, *slight* for small focal irregularities, *low moderate* for occasional (less than 75 percent) obstructions at several points or one significant lesion, *high moderate* for one vessel occlusion or numerous lesions and *severe* for two or more significant or occlusive lesions. The grade of diffuseness of atherosclerosis was assessed on the basis of the number and confluence of atheromas. Tortuosity of the epicardial coronary arteries[47] was graded as *slight,* when only gentle waviness of the vascular course was seen, to *severe* when arteries formed loops and hairpin curves in their course. The degree of development of coronary arterial collateral connections was assessed on the basis of their size and tortuosity.[48] A diameter (D_{Th}) for a theoretic single coronary artery supplying blood to the heart[47,49] was calculated from measurements of the diameters of the major left and right coronary arteries by the formula: $(D_{Th})^3 = (D_{Right})^3 + (D_{Left})^3$.

Histology: We reviewed representative histologic sections of hematoxylin-eosin–stained heart, pancreas and kidney tissue, without knowledge of the clinical history. Interstitial vacuolar change in the myocardium and intimal disease of intramyocardial coronary arteries were graded. We made an overall assessment of renal glomerular disease as well as of specific renal disease such as diffuse and nodular intercapillary glomerulosclerosis and intrarenal fibroelastosis. Random sections of pancreatic tissue were evaluated for hyalinization of the islets, hyperplasia of the islets and interstitial fat. Grading of pathologic variables represented the consensus of two observers, and was made without knowledge of the clinical features of the patient.

Analysis of data: Correlation coefficients (Pearson's r) were calculated and examined for all pairs of the 54 variables. These findings were used in part as the basis for deciding which variables would be of interest in subsequent analyses. Forward and backward stepwise multivariate regression analyses were then performed using each of 26 features (indicated by an asterisk in Table I) as the dependent variable or variable to be predicted.[50,51] In the forward regression, variables were added singly until no further variables achieved a 0.01 level of significance with the dependent variable. The 0.01 level of significance was selected because of the high likelihood of spurious results with more permissive significance levels when so many variables (that is, 26) were being evaluated.

TABLE I

Variables Examined After Initial Screening

Clinical Findings	Pathologic Findings
Age*	Panniculus thickness*
Severity of diabetes*	Heart weight*
Duration of diabetes*	Overall coronary arterial atherosclerosis*
Dietary therapy	Number of diseased coronary arteries
Oral hypoglycemic agent therapy	Diffuseness of coronary atherosclerosis
Insulin therapy	Coronary arterial collaterals
Episodes of acidosis*	Epicardial coronary arterial tortuosity*
Episodes of coma*	Diameter of theoretical coronary artery
Retinopathy*	Intramyocardial arterial disease*
Urinalysis	Vacuolar change of myocardium
Renal failure*	Number of myocardial infarcts*
Hypertension*	Kidney weight*
Cerebrovascular accidents*	Intrarenal intimal fibroelastosis*
Peripheral vascular disease*	Overall glomerular disease*
Peripheral neuropathy*	Nodular intercapillary glomerulosclerosis
Amputations*	Diffuse intercapillary glomerulosclerosis
Angina*	Liver weight*
Congestive heart failure*	Hyalinization of pancreatic islets*
	Hyperplasia of pancreatic islets*
	Pancreatic interstitial fat
	Generalized atherosclerosis
	Cerebral atherosclerosis
	Pulmonary atherosclerosis

* Variables used in multivariate regression analysis.

FIGURE 1. Postmortem coronary arteriograms from patients with diabetes mellitus. **Left,** the heart of a 48 year old man with a 13 year history of diabetes mellitus requiring insulin therapy and complicated by peripheral neuropathy and retinopathy that had progressed to blindness. There is virtually no coronary arterial atherosclerosis. **Right,** the heart of a 67 year old woman with a 7 year history of diabetes mellitus treated with oral agents and complicated by leg amputation, cerebral infarcts and ischemic heart disease. The coronary atherosclerosis is extremely severe with significant obstructions or occlusions of several major arteries.

Control patients: Age- and sex-matched control nondiabetic patients whose heart had also been studied at autopsy after postmortem coronary arteriography and fixation in distension were selected. These patients were evaluated as described previously for body and organ weights, pathologically identified myocardial infarcts and the various semiquantitative estimates made from the postmortem coronary arteriograms. The data from these patients were compared with the Student's t test with data from the corresponding diabetic patients.

Results

Severity of diabetes versus severity of coronary disease: Among the 54 variables studied in the 185 patients with diabetes mellitus of adult onset, several were excluded from further assessment because data were (1) frequently not available (serum creatinine, urea nitrogen and cholesterol, pack-years of smoking and family history of diabetes), (2) deemed inconclusive (hematocrit, electrocardiographic changes, weight and height), (3) not further analyzed (race and sex), or (4) found redundant after pairwise correlation (obesity replaced by panniculus thickness, and age at onset of diabetes replaced by duration of disease). The remaining 41 variables (Table I) were examined. Significant correlations with postmortem coronary arteriographic findings (Fig. 1) are noted in Table II. Despite positive correlations between coronary artery disease and both clinically determined angina and autopsy-documented myocardial infarction, there was no significant association between overall coronary arterial atherosclerosis and either the duration or the severity of diabetes mellitus.

TABLE II

Simple Correlation Coefficients for all Among 40 Variables That Significantly ($p < 0.05$) Correlated With Overall Coronary Arterial Atherosclerosis

Variable	Pearson's r	Degrees of Freedom
Renal failure	−0.22*	181
Angina	+0.41†	183
Number of diseased coronary arteries	+0.89†	183
Diffuseness of coronary atherosclerosis	+0.81†	183
Coronary arterial collateral vessels	+0.80†	178
Epicardial coronary arterial tortuosity	−0.36†	182
Diameter of theoretic coronary artery	−0.49†	155
Vacuolar change of myocardium	+0.42†	176
Number of myocardial infarcts	+0.64†	180
Generalized atherosclerosis	+0.41†	182

* $p < 0.01$; † $p < 0.001$.

Histopathologic change versus clinical diabetes: The histopathologic changes in the heart, kidney and pancreas (Fig. 2) that had significant correlations with clinically determined diabetes are given in Table III. Hyalinization of the pancreatic islets was significantly correlated with duration of diabetes ($p < 0.05$), whereas hyperplasia of the islets correlated with severity of diabetes ($p < 0.01$). Intrarenal intimal fibroelastosis correlated with the severity of diabetes ($p < 0.01$) and the duration of disease ($p < 0.001$). Both diffuse and nodular intercapillary glomerulosclerosis showed significant correlation with the severity of diabetes and duration of disease. Intramyocardial arterial disease was correlated with the duration of diabetes ($p < 0.05$). Vacuolar change of myocardium had no correlation with the diabetic state, but did correlate with severity of coronary arterial atherosclerosis and ischemic myocardial injury. There were no significant correlations between severity of diabetes and either systemic, pulmonary or cerebral atherosclerosis. When patients were separated into three groups—those receiving no therapy or dietary treatment only, those receiving oral hypoglycemic

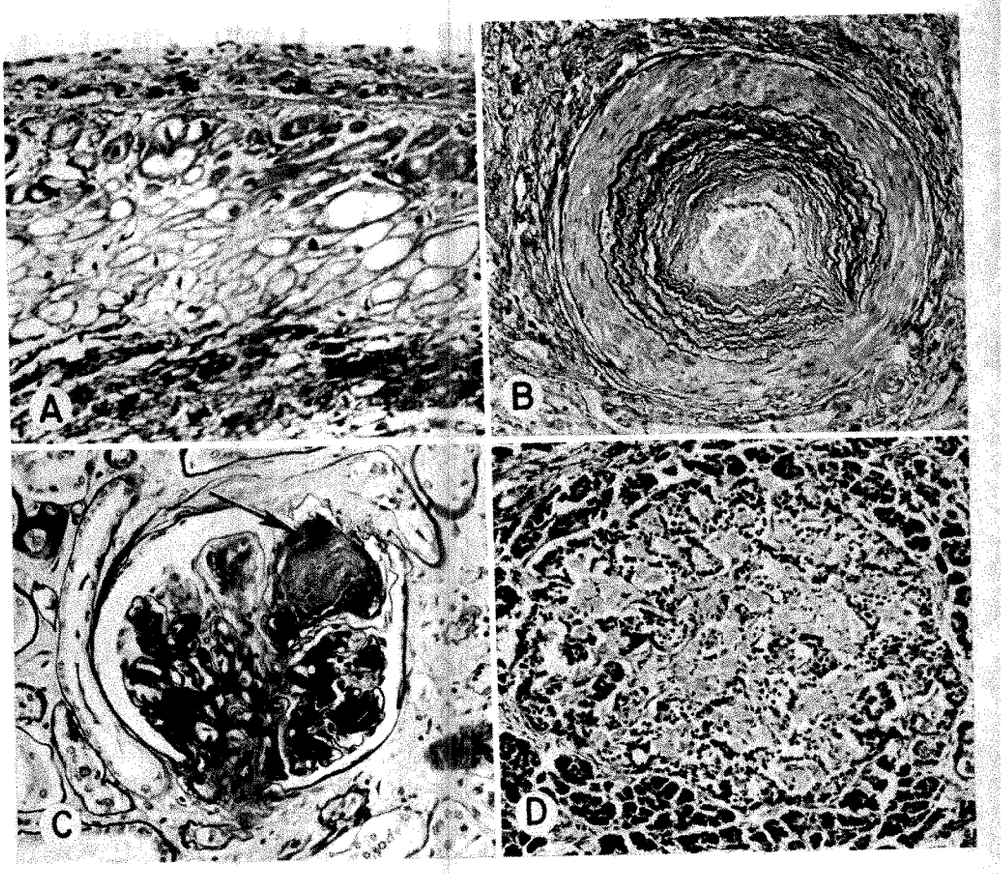

FIGURE 2. Histologic sections. **A,** subendocardial vacuolar change of myocardium. (hematoxylin-eosin, ×250, reduced by 26 percent.) **B,** intrarenal intimal fibroelastosis of an artery. (Verhoeff-van Gieson elastic stain, ×185, reduced by 26 percent.) **C,** a glomerulus showing nodular (**arrow**) and diffuse intercapillary glomerulosclerosis. (periodic acid-Schiff, ×350, reduced by 26 percent.) **D,** pancreatic islet of Langerhans with hyalinization. (hematoxylin-eosin, ×185, reduced by 26 percent.)

agents, and those receiving insulin—we found no significant differences among the coronary arterial atherosclerotic variables.

The results of the 26 starred variables in Table I that were entered in the forward multivariate regression are listed in Table IV.[50,51] Angina correlated positively with coronary artery disease and negatively with cerebrovascular accidents. Overall coronary arterial atherosclerosis correlated positively with the number of myocardial infarcts and angina but negatively with congestive heart failure and tortuosity. There were no significant correlations between severity of diabetes and coronary arterial atherosclerosis.

Control group findings: The age- and sex-matched control group (Table V) demonstrated significantly lower overall coronary arterial atherosclerosis ($p < 0.002$) than did the diabetic patients. In addition, the number of myocardial infarcts ($p < 0.001$), number of diseased coronary arteries ($p < 0.001$), diffuseness of coronary atherosclerosis ($p < 0.005$) and presence of coronary arterial collateral channels ($p < 0.001$) were significantly different from findings in diabetic patients.

Discussion

Influence of diabetes on severity of coronary artery disease: We were surprised to find that there was no correlation between the severity or duration of diabetes mellitus of adult onset and the severity of coronary arterial atherosclerosis in the patients studied. However, comparison of these patients to an age- and sex-matched control group showed that the diabetic patients did indeed have more coronary atherosclerosis, a finding in accord with previous data.[1,5–16] Although we found no significant differences in either heart weight or the tortuosity of the coronary vessels between the two groups, the diabetic patients showed an increase

TABLE III

Pathologic Changes Significantly Correlated ($p < 0.05$) With Severity and Duration of Diabetes

Variable	Pearson's r	Degrees of Freedom
Severity of diabetes with:		
Intrarenal intimal fibroelastosis	+0.24†	170
Overall glomerular disease	+0.36‡	170
Nodular intercapillary glomerulosclerosis	+0.37‡	170
Diffuse intercapillary glomerulosclerosis	+0.32‡	170
Hyperplasia of pancreatic islets	+0.20†	166
Duration of diabetes with:		
Intramyocardial arterial disease	+0.15*	171
Intrarenal intimal fibroelastosis	+0.24‡	170
Overall glomerular disease	+0.27‡	170
Nodular intercapillary glomerulosclerosis	+0.30‡	170
Diffuse intercapillary glomerulosclerosis	+0.25‡	170
Hyalinization of pancreatic islets	+0.15*	166

TABLE IV

Forward Multivariate Regression Analysis Predicting Selected Variables*

Retinopathy	= 2.44 + 0.22 renal failure + 0.27 overall glomerular disease + 0.25 severity of diabetes
Renal failure	= 5.92 + 0.32 overall glomerular disease + 0.36 congestive heart failure + 0.26 retinopathy − 6.04 number of myocardial infarcts
Hypertension	= 15.70 + 0.38 overall glomerular disease + 8.49 cerebral vascular accident
Angina	= 6.77 + 0.45 overall coronary arterial atherosclerosis − 13.32 cerebral vascular accident
Congestive heart failure	= −2.65 + 0.32 renal failure + 0.08 heart weight − 0.50 panniculus thickness
Heart weight	= 303.58 + 1.50 congestive heart failure + 2.33 kidney weight + 2.63 intramyocardial arterial disease
Overall coronary arterial atherosclerosis	= 57.15 + 12.51 number of myocardial infarcts − 0.22 congestive heart failure + 0.18 angina − 0.35 epicardial coronary arterial tortuosity
Epicardial coronary arterial tortuosity	= 86.39 − 0.16 overall coronary arterial atherosclerosis − 0.21 kidney weight − 0.02 heart weight
Intrarenal intimal fibroelastosis	= 28.88 + 0.25 overall glomerular disease + 0.24 age + 0.08 hypertension

* Independent variables (* in Table I) enter at a significance level of $p < 0.01$. Thirty-four patients were excluded because of insufficient data.

in angiographically determined numbers of diseased coronary vessels, diffuseness of coronary disease and collateralization of coronary arteries. In contrast, in a previous coronary angiographic study[38] of 35 diabetic and 35 nondiabetic patients, there were no differences between the two groups in mean luminal diameters of coronary arteries. Although Hamby et al.[29] evaluated patients with angina and found the extent of coronary artery disease reflected in both the number of vessels involved and the total coronary score to be the same for diabetic and nondiabetic patients, Dortimer et al.[34] found that adult diabetic patients with chest pain had more coronary artery disease but no more diffuse or inoperable disease. Our study, which reports the angiographic findings of both symptomatic and asymptomatic diabetic patients regardless of cause of death and clinical course, supports the studies that have indicated more coronary disease in this population.

TABLE V

Comparison of Coronary Artery Disease in 185 Diabetic Patients and 185 Age- and Sex-Matched Control Patients

Variable	Diabetic Patients*	Control Patients*	p†
Overall coronary arterial atherosclerosis	49.9 ± 29.7	39.7 ± 31.5	<0.002
Number of diseased coronary arteries	1.4 ± 1.2	1.0 ± 1.2	<0.001
Diffuseness of coronary atherosclerosis	41.6 ± 29.1	32.8 ± 29.8	<0.005
Coronary arterial collaterals	32.1 ± 32.1	20.7 ± 31.7	<0.001
Epicardial coronary arterial tortuosity	52.8 ± 17.3	55.5 ± 16.3	<0.1
Number of myocardial infarcts	1.2 ± 1.2	0.8 ± 0.9	<0.001

* Mean ± standard deviation; † Student's *t* test.

Lack of influence of duration and severity of diabetes: On the other hand, this group of diabetic patients by itself failed to show significant correlations between coronary arterial atherosclerosis and the duration or severity of diabetes. Significant associations between clinically determined diabetes and diabetic changes in the kidney, pancreas and the intima of intramyocardial vessels indicated that the severity of disease was indeed manifested in our patients in the form of pathologic tissue changes well recognized as being attributable to diabetes.[52] Prediction of selected variables by multivariate regression analysis (Table IV)[50,51] showed, at the significance level chosen, that severity of diabetes mellitus predicted only retinopathy. Retinopathy in turn entered into the prediction of renal failure, which was also dependent on glomerular disease and congestive heart failure. Angina pectoris was associated with severity of coronary atherosclerosis, but congestive heart failure was a function of renal failure and heart weight. Peculiar negative associations, such as that between angina and cerebrovascular accident and that between overall coronary arterial atherosclerosis and congestive heart failure, may simply reflect the fact that patients who came to autopsy with one condition had not yet experienced the other. Epicardial coronary arterial tortuosity, which is most marked in elderly patients with a small heart,[47] showed the expected associations, although its relation to kidney

weight is not understood. Another predicted association system is provided by intrarenal intimal fibroelastosis, which showed the expected dependence on glomerular disease, age and hypertension.

Clinical implications: Although our diabetic patients had an increased incidence of atherosclerosis their coronary angiograms did not reflect an angiographically evident progressive cardiac vascular disease. Neither the severity nor the duration of diabetes as determined clinically and substantiated by histopathologic changes in the kidney and pancreas was reflected in the severity of large vessel coronary disease. Although subtle changes in the interstitium[31–33] or small vessels of the heart[29,30] may represent cardiac analogs to diabetic retinal and kidney disease, causing the functional abnormalities of the heart as documented by some investigators,[31,40] the duration and severity of diabetes is not seen as determining the severity of angiographically discernible coronary disease. Our results suggest that the progress of large vessel coronary atherosclerotic disease in diabetes mellitus of adult onset takes place independently of the progress of the diabetes itself.

Survival, subsequent myocardial infarction and current anginal status were determined for 90 nearly consecutive patients who underwent coronary arteriography at the Johns Hopkins Hospital between 1960 and 1967. All patients had at least one coronary arterial narrowing equal to or greater than 70 percent; 78 of 90 patients would be candidates for coronary bypass surgery by present criteria. Twenty-nine of the 78 surgically "suitable" patients died of cardiac causes; 7 of 49 survivors sustained an acute myocardial infarction (mean follow-up period 9.9 years). Patients with a 70 percent or greater narrowing proximal to the first septal branch of the left anterior descending coronary artery had a significantly greater mortality compared with patients with equivalent narrowing distal to the first septal branch or with patients without 70 percent or greater narrowing of the left anterior descending artery. The patients with a 70 percent or greater narrowing of the left anterior descending artery who died were those with a significant narrowing in at least one other major coronary artery. Multivariate stepwise discriminate function analysis of all clinical, electrocardiographic (except stress electrocardiographic) and arteriographic variables identified three independent predictors of mortality: (1) the simultaneous occurrence of a narrowing in left anterior descending and right coronary arteries, (2) prior myocardial infarction; and (3) 70 percent or greater narrowing proximal to the first anterior descending septal branch. When stress electrocardiographic findings were included, a "positive" stress electrocardiographic test was also an independent predictor of mortality.

The distribution and extent of atherosclerosis within the coronary arterial circulation is an important determinant of subsequent mortality.[1] Although previous reports have shown a relation between survival and extent of atherosclerotic disease[2] or the number of major coronary arteries narrowed,[3–6] the only specific narrowing demonstrated to be associated with a high mortality rate is 50 percent or greater obstruction of the left main coronary artery.[7–11] The patients who underwent coronary arteriography at the Johns Hopkins Hospital between 1960 and 1967 were examined to determine whether a significant narrowing at locations other than the left main coronary artery was associated with a high risk of dying. The relative contribution of historical, electrocardiographic and coronary arteriographic findings to the occurrence of death after arteriography was examined using multivariate stepwise discriminate function analysis.

Methods

Patient group: During the 8 year period between 1960 and 1967, 350 patients underwent selective coronary arteriography at the Johns Hopkins Hospital. Of these patients, 104 were excluded from this study because the origin of their cardiac disease was considered to be primarily valvular or myocardial and not atherosclerotic. In two patients, the arteriogram was unsatisfactory for interpretation. Eighteen other patients were excluded because they underwent internal mammary arterial implantation within 1 year of coronary arteriography.

Of the remaining 224 patients, 90 had 70 percent or greater narrowing of at least one major coronary artery and might have been considered for coronary bypass grafting if it had been available at the time they underwent arteriography. One hundred thirty-four patients were excluded from the study because no major coronary artery was narrowed by 70 percent or more.

Patient follow-up: Follow-up information on all 90 patients was available through January 1975 either by reexamination of the patient at the Johns Hopkins Hospital or by letter or phone call to the patient or referring physician. If a patient died, the cause and circumstances of death were ascertained from the patient's physician and death certificate. Three patients underwent coronary bypass graft surgery at 44, 65 and 82 months, respectively, after arteriography. The follow-up period for these three patients was only until the time of operation. There were 32 deaths in this series; twenty-nine deaths were considered of cardiac origin and 3 of noncardiac origin. Two patients died of cancer (52 and 83 months, respectively, after arteriography) and one in an automobile accident (27 months after arteriography); they were considered alive until that point and then "lost to follow-up."

Clinical data: The following information was available from the patient's hospital record: age, sex, duration and severity of angina before arteriography, history of a previous myocardial infarction, history of congestive failure, cardiothoracic ratio by chest roentgenogram and fasting serum cholesterol level. Functional disability due to chest pain was defined according to the New York Heart Association classification.[12] Congestive heart failure considered secondary to left ventricular dysfunction was noted by the presence of bilateral pulmonary rales, hepatomegaly or pedal edema, or the presence of orthopnea or paroxysmal nocturnal dyspnea. Standard posteroanterior and lateral chest X-ray films were obtained in all patients. Cardiomegaly was defined as a cardiothoracic ratio of greater than 50 percent on the posteroanterior chest X-ray film.

Electrocardiographic findings: The electrocardiogram at rest was interpreted as normal or abnormal according to the criteria of Rose and Blackburn.[13] An electrocardiogram at rest was considered abnormal if at least one of the following was present: a Q wave of 0.04 second's duration, an S-T segment shift of at least 1 mm (either depression or elevation), left bundle branch block or atrial fibrillation.

A Master double two-step exercise electrocardiographic test was performed in 68 patients at the time of coronary arteriography. None of these 68 patients had evidence of either left ventricular hypertrophy or left bundle branch block in the electrocardiogram at rest that precluded interpretation of the stress electrocardiographic changes. Ten leads were recorded simultaneously before, during and after exercise.[14] The end point of a Master double two-step test was the completion of a specified number of trips across two steps. The number of trips was determined by the patient's sex, age and weight.[15] A stress test was interpreted as positive when the electrocardiogram manifested horizontal or downsloping S-T segment depression of at least 1 mm for 0.08 second on three consecutive beats. Available stress tests were reviewed. If a patient's stress test was not available for review by us, we obtained a report from the hospital record describing the test as positive or negative by these criteria.

Coronary arteriography: Selective coronary arteriography using the brachial arterial (Sones) technique was performed in all patients.[16] Multiple cineradiographs in each patient were reviewed by one author (L.S.C.G.) without knowledge of the patient's subsequent clinical course. The coronary arterial system was divided into 15 segments as proposed by a committee of the American Heart Association,[17] and the most severe luminal narrowing for each segment was recorded (in percent) as (a) 30, (b) 50, (c) 70, (d) 90 or "near-total" occlusion, (e) 100 (or total), or (f) no narrowing or irregularity present. For purposes of analysis, each patient was considered to have one, two or three vessel disease depending on whether the right, left anterior descending or circumflex artery was narrowed by 50 percent or more. Three patients with a narrowing of at least 50 percent of the left main coronary artery were considered to have a narrowing of both the left anterior descending and left circumflex coronary arteries. Because only three patients had significant left main disease and only one died during the follow-up period, dates on these three patients were best analyzed separately.

A schematic drawing of the left main and left anterior descending arteries according to the American Heart Association classification proposal is shown in Figure 1. Patients were considered to have "proximal" left anterior descending disease if there was a 70 percent or greater narrowing proximal to the first septal branch (segment 5 or 6) or "distal" anterior descending disease if such narrowing was in the segment immediately distal to the first septal branch (segment 7). Filling by collateral channels of any coronary segment was also noted.

Left ventriculography was not performed in these patients. This procedure was not a routine part of the catheter evaluation of coronary heart disease at The Johns Hopkins Hospital until 1968. Hence, the influence of left ventricular contraction patterns on survival could not be analyzed in these patients.

Surgical suitability: Ninety patients were classified as "suitable" or "unsuitable" candidates for coronary bypass graft surgery by current 1978 criteria. "Suitability" for such surgery was judged on the basis of three criteria: (1) narrowing of 70 percent or more in at least one major coronary artery; (2) the characteristics of the coronary arterial segment distal to the obstruction, and (3) left ventricular performance. To be suitable for coronary bypass surgery, the distal coronary arterial segment had to be opacified by either anterograde or collateral filling and have an internal diameter of at least 1 mm *and* be free of plaque so that the internal diameter was not

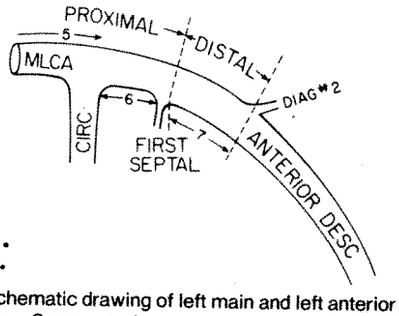

FIGURE 1. Schematic drawing of left main and left anterior descending coronary artery. Segments drawn according to American Heart Association proposal.[15] ANTERIOR DESC = left anterior descending artery; CIRC = circumflex artery; DIAG #2 = second diagonal branch of left anterior descending artery; DISTAL = coronary segment 7 (7) that begins *distal* to origin of first septal branch; FIRST SEPTAL = first septal branch of left anterior descending artery; MLCA = left main coronary artery; PROXIMAL = coronary segments *proximal* to first septal branch (segments 5 and 6; 5 = (segment 5) left main coronary artery; 6 = (segment 6) left anterior descending arterial segment proximal to and including origin of first septal branch; 7 = (segment 7) left anterior descending segment beginning distal to origin of first septal branch and extending to point where it forms an angle in the right anterior oblique projection, often coinciding with the origin of the second diagonal branch.

reduced by 50 percent or more at the usual site of bypass graft and coronary arterial anastomosis or distal to this location. A distal coronary artery was considered unsuitable for bypass surgery if any one of the criteria was absent. A patient was considered "unstable" for bypass surgery on the basis of presumed severe left ventricular dysfunction if the cardiothoracic ratio was greater than 50 percent on the plain chest X-ray film *and* left ventricular end-diastolic pressure was greater than 20 mm Hg *and* the patient had congestive left ventricular failure on clinical examination. These data were reviewed for each patient by one of us (L.S.C.G.) without knowledge of the patient's subsequent clinical course.

Statistical methods: Contingency table analysis utilizing chi-square tests of significance was used to test individually the effect of independent clinical, electrocardiographic or arteriographic variables against the dichotomous outcome of subsequent survival or death. These variables included sex; degree of anginal disability; history of a previous myocardial infarction; history of congestive heart failure; cardiothoracic ratio greater than 50 percent on a chest X-ray film; normality or abnormality of the electrocardiogram at rest and during stress; the number of coronary arteries narrowed by 50 percent or more; presence or absence of 50 percent or greater narrowing of the left main coronary artery or of the right, left anterior descending or left circumflex artery; presence or absence of 70 percent or greater narrowing proximal or distal to the first left anterior descending septal branch; and presence or absence of collateral filling of the distal left anterior descending artery. Continuous variables such as age, cholesterol level and duration of angina before arteriography were similarly compared with Student's *t* test.

To consider the actuarial survival experience, we constructed cumulative survival curves that took into account various lengths of follow-up study. These curves were fitted by the method of Kaplan and Meier.[18] Factors were then examined for their possible effect on survival by comparing these survival curves using Peto's analysis.[19,20]

Multivariate stepwise discriminate function analysis was used to consider simultaneously all independent variables.[21–24] Dichotomous variables, such as male or female or the presence or absence of prior infarction, were entered as 0, 1 variables. Continuous variables, such as age and duration of angina, were used allowing for both linear and nonlinear effects. The coronary arteriographic variables were entered as both continuous and dichotomous variables. Each patient was entered as having 50 percent or greater narrowing of one, two or three arteries. The location of the narrowing 70 percent or greater of the left anterior descending artery as proximal or distal to the first septal branch was entered as a dichotomous variable. The percent narrowing of each of the three major arteries was analyzed as a continuous variable and then reanalyzed as a dichotomous variable separated at 70 percent or greater narrowing. Terms of interaction for interdependence between vessels as well as location of the 70 percent or greater narrowing in the left anterior descending artery were also included in the analysis.

Multivariate stepwise discriminate analysis ranks the independent variables, including the terms of interaction, in order of their contribution to discrimination between those who survive or die and allows for significance testing of the contribution at each step. It is therefore possible to assess whether a variable makes a significant contribution over and above the other factors included. The significance levels derived by this technique are statistical tests of significance by which additional predictive information is provided by a specific variable over and above the information provided by the variables already tested.

Results

Surgical suitability: Of the 224 patients whose data were reviewed, 90 patients had 70 percent or greater narrowing of at least one coronary artery. Twelve of these patients were considered unsuitable candidates for coronary bypass grafting by current criteria because the distal coronary arterial segment or segments were considered unsuitable for grafting (nine patients) or left ventricular function was presumed to be very poor (three patients).

Clinical follow-up: Follow-up information on these 90 patients at a mean interval (± standard error of the mean) of 9.9 ± 0.2 years after coronary arteriography is recorded in Table I. The mortality rate was higher in the 12 patients who were considered unsuitable for coronary bypass grafting (67 percent), compared with the 78 patients who were considered suitable candidates (37 percent). Of the 78 patients who would have been candidates for bypass surgery by current criteria, 29 died of cardiac causes and 49 were alive at the time of follow-up study. Seven (14 percent) of these 49 survivors sustained a nonfatal myocardial infarction after coronary arteriography and 39 (80 percent) continued to have angina pectoris; however, 31 (63 percent) were employed full time.

The 78 patients considered to be surgical candidates have been grouped by the degree of anginal disability at the time of coronary arteriography (Fig. 2). There was

TABLE I

Survival After Coronary Arteriography

	Surgical Candidates*	Not Surgical Candidates*
Patients (n)	78	12
Deaths	29 (37%)	8 (67%)
Acute infarction/survivors	7/49 (14%)	0/4
Continued angina/survivors	39/49 (80%)	3/4 (75%)
Engaged in full-time work/survivors	31/49 (63%)	3/4 (75%)

* See text for description of "surgical" and "not surgical" candidates.

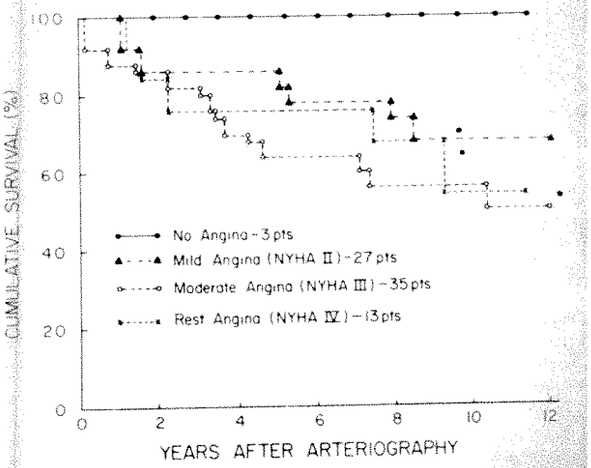

FIGURE 2. Influence of anginal disability on expected cumulative survival. NYHA = New York Heart Association; pts. = patients.

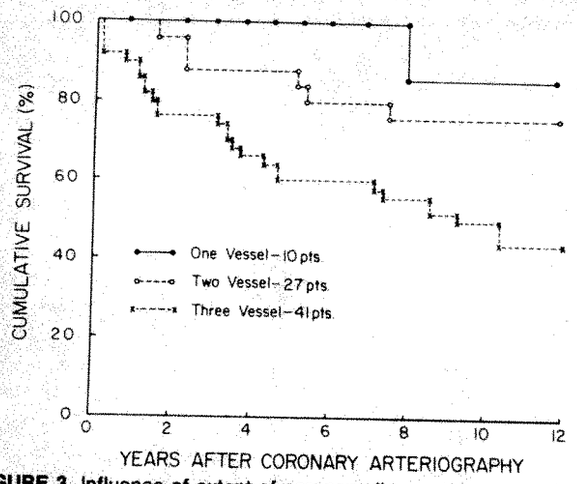

FIGURE 3. Influence of extent of coronary disease on expected cumulative survival. Extent of disease is defined as one, two or three major arteries narrowed by 50 percent or more. pts. = patients.

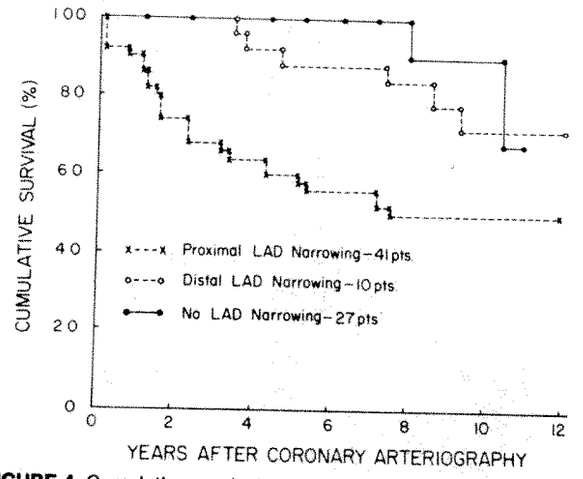

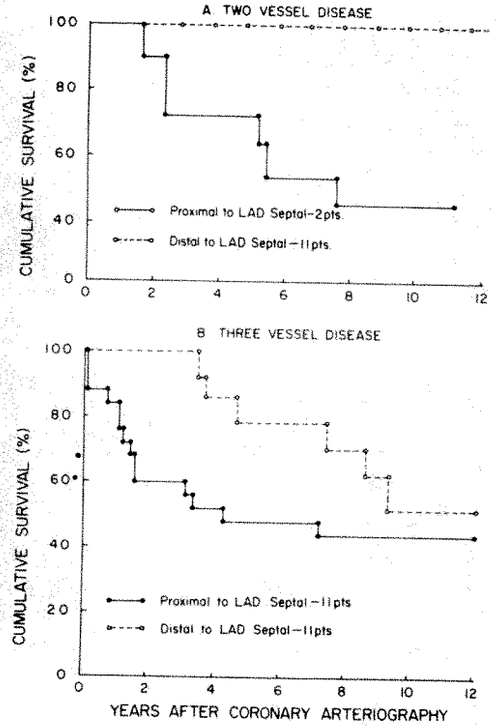

FIGURE 4. Cumulative survival of patients with 70 percent or greater narrowing proximal to the first left anterior descending (LAD) septal branch (41 patients), 70 percent or greater narrowing in a coronary segment distal to the first anterior descending septal branch (27 patients), and those patients without 70 percent or greater narrowing in either the anterior descending or left main coronary arteries (10 patients).

no significant difference in mortality rates among these groups. Mild anginal symptoms (New York Heart Association class II) did not appear to predict improved survival in the 78 patients in this study.

Survival in patients with one, two or three vessel disease: A survival analysis of the 78 patients, based on whether one, two or all three major coronary arteries were narrowed by at least 50 percent, is shown in Figure 3. The mean follow-up period for these patients was 9.9 years. There was a significant difference in these survival curves ($p < 0.02$). Furthermore, the linear trend across the number of vessels was significant ($p < 0.02$). Ten patients had single vessel disease, including seven who had, as the only obstructive lesion, narrowing of the left anterior descending artery proximal to the first septal perforating branch. Only one patient with single vessel disease died. This man had 90 percent narrowing of the left anterior descending artery proximal to the first septal branch. In this small patient group, those with single vessel disease had a good outcome, including those patients with significant narrowing before the first septal branch of the left anterior descending artery.

GURE 5. Cumulative survival of patients with either two vessel (**A.**) three vessel (**B.**) coronary artery disease. Each group is subdivided :cording to whether the 70 percent or greater narrowing is located oximal or distal to the first septal perforator branch of the left anterior :scending (LAD) artery. pts. = patients.

Influence of left anterior descending arterial narrowing on survival: The influence of narrowing of a particular artery on survival after arteriography was examined. Narrowing of the left anterior descending artery by at least 70 percent was found to influence adversely subsequent mortality. (This was true only in the presence of significant disease in at least one other major artery.) Seventy patients were available for follow-up at 8 years. Twenty-four (40 percent) of the 60 patients with 70 percent or greater narrowing of the left anterior descending or left main coronary artery were dead compared with none of the 10 patients with either no or less than 70 percent narrowing of the left anterior descending artery ($p < 0.05$). As will be described later, most of the deaths in patients with a 70 percent or greater narrowing of the left anterior descending artery occurred in those who also had a significant narrowing of at least one other major coronary artery.

Forty-one patients had at least 70 percent narrowing proximal to the first septal branch of the left anterior descending artery; in 38 of the 41 this narrowing was in the anterior descending artery (Fig. 1, segment 6); in 3 it was in the left main coronary artery (Fig. 1, segment

TABLE II

Clinical Findings of Patients With 70 Percent or Greater Narrowing Proximal or Distal to First Septal Branch of Left Anterior Descending Artery

	Proximal (41 patients)	Distal (27 patients)	p
Age (mean ± SD) (yr)	42.1 ± 7.6	43.6 ± 8.1	NS
Male (%)	90	85	NS
Cholesterol (mean ± SD) (mg/100 ml)	284 ± 69	289 ± 83	NS
Prior infarction (%)	34	26	NS
Duration of angina (mean ± SD) (mo)	41.4 ± 43.4	34.1 ± 32.1	NS
Abnormal rest electrocardiogram (%)	59	48	NS

NS = not significant; p = probability; SD = standard deviation.

TABLE III

Collateral Filling of Left Anterior Descending Artery (LAD) and Death Within 8 Years After Arteriography*

Severity of Proximal LAD Narrowing	Collateral Filling of Distal LAD		No Collateral Filling of Distal LAD	
	Cases	Deaths at 8 yr	Cases	Deaths at 8 yr
100% occlusion	12	3 (25%)	0	0
90–99% narrowing	6	5 (83%)	28	10 (37%)
70–89% narrowing	4	4 (100%)	10	2 (20%)
	22	12 (55%)	38	12 (32%)

* Only patients with at least 8 years of follow-up study are included in this table.

5). In 27 patients, the 70 percent narrowing in the anterior descending artery was in segment 7 (Fig. 1) just distal to the origin of the first septal branch. Survival data in these two subgroups as well as in the 10 patients who did not have a 70 percent or greater narrowing in the anterior descending artery are shown in Figure 4. The poorest outcome was associated with narrowing proximal to the first septal branch and the most favorable was noted in patients without significant disease of the anterior descending artery. Patients with anterior descending arterial narrowing distal to the first septal branch has an intermediate outcome ($p < 0.04$). The linear trend across these three variables is significant ($p < 0.02$).

• *The influence of proximal and distal left anterior descending arterial disease* was examined separately in patients with two and three vessel disease (Fig. 5). Although the patient groups are small and statistically significant differences in survival were found only in the group with two vessel disease, mortality was greater in patients with disease of the proximal left anterior descending artery in both groups.

The clinical characteristics were compared in the 41 patients with 70 percent or greater narrowing proximal to the first septal branch and in the 27 patients with significant narrowing distal to this branch (Table II). There were no significant differences between these two groups with respect to age, sex, history of prior myocardial infarction or duration of angina before arteriography, presence of an electrocardiographic abnormality at rest or serum cholesterol level.

Collateral filling of left anterior descending artery: Of the 68 patients with at least 70 percent narrowing of the left anterior descending or left main coronary artery, 24 had collateral filling of the distal anterior descending artery from either the left circumflex or the right coronary artery and 44 patients did not. Fourteen (58 percent) of the 24 patients with collateral filling of the distal anterior descending artery died during the follow-up period compared with 12 (27 percent) of the 44 patients without collateral vessels to the left anterior descending artery. Survival analysis of these two patient groups revealed a significantly higher mortality rate among patients with collateral filling of the left anterior descending artery than on patients without collateral vessels ($p < 0.04$) (Fig. 6). The severity of the proximal narrowing of the left anterior descending artery in these two groups and the number of patients who died within each group after arteriography are shown in Table III. The number of patients with a total occlusion of the proximal left anterior descending artery was larger in the group with collateral vessels. Nevertheless, the presence of collateral vessels to the distal vascular segment may be an angiographic marker of more "severe" disease and not necessarily provide increased protection against death.

Electrocardiogram at rest: Of the 78 surgically suitable patients, 44 had an abnormal electrocardiogram at rest at the time of coronary arteriography. Twenty patients had a Q wave, 19 had an S-T segment shift of more than 1 mm, 4 had left bundle branch block and 1 had atrial fibrillation. When all four groups are considered as having an abnormal electrocardiogram at rest, survival analysis shows that there was greater mortality in patients with an abnormal electrocardiogram at rest than in patients with a normal electrocardiogram ($p < 0.03$) (Fig. 7).

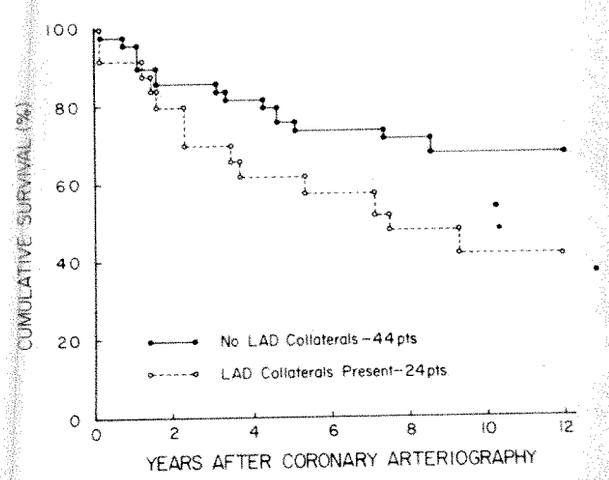

FIGURE 6. Cumulative survival of patients with 70 percent or greater narrowing in the left main or left anterior descending (LAD) coronary artery who have collateral vessels (24 patients) and those who do not have collateral vessels (44 patients) to the distal anterior descending artery on arteriography.

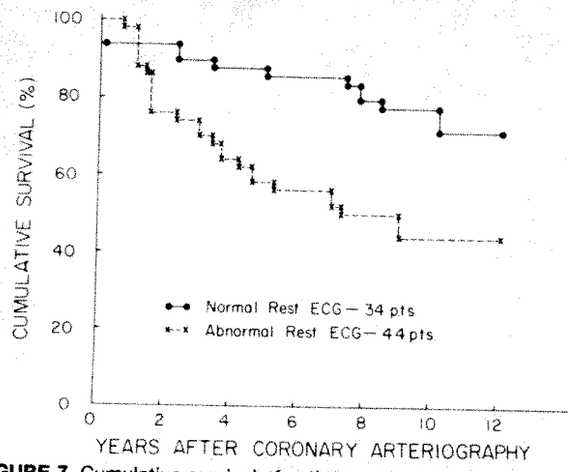

FIGURE 7. Cumulative survival of patients with either a normal or an abnormal electrocardiogram at rest (ECG). pts. = patients.

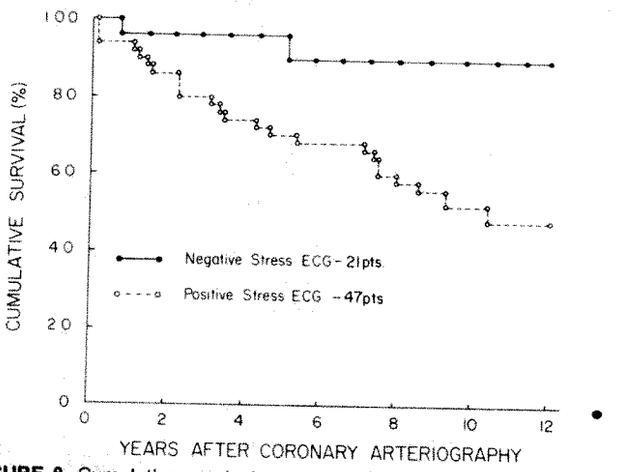

FIGURE 8. Cumulative survival of patients (pts.) with a negative or positive stress electrocardiogram (ECG).

Stress electrocardiogram: Sixty-eight of the 78 surgically suitable patients underwent a double Master's exercise electrocardiogram. Analysis of survival revealed a poorer outcome in patients with a positive stress electrocardiogram than in those with a negative stress test ($p < 0.02$) (Fig. 8). Fifty-eight of the 68 patients with 70 percent or greater narrowing in the left main or left anterior descending coronary artery underwent stress electrocardiography. These patients were subclassified according to whether the 70 percent or greater narrowing was proximal or distal to the first anterior descending septal branch, and whether the stress test was positive or negative for S-T segment shift. Survival analysis showed the poorest outcome in patients with a 70 percent or greater narrowing in the proximal left anterior descending artery and a positive stress test and the best outcome in patients with a 70 percent or greater narrowing of the distal anterior descending artery and a negative stress test. The outcome in patients with a narrowing of the proximal anterior descending artery but with a negative stress test and of those with a distal narrowing but with a positive stress test was intermediate ($p < 0.02$). (Fig. 9).

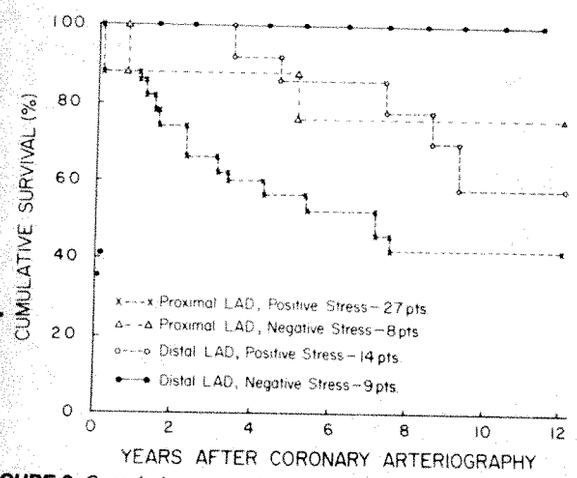

FIGURE 9. Cumulative survival of patients with 70 percent or greater narrowing proximal to the first septal perforator branch of the anterior descending artery and a positive (27 patients) or negative (8 patients) stress electrocardiogram; 70 percent or greater narrowing in segment distal to the first septal branch and a positive (14 patients) or negative (9 patients) stress electrocardiogram. LAD = left anterior descending coronary artery.

Multivariate analysis: Many independent variables when considered separately were noted to have an influence on survival. A multivariate stepwise discriminate analysis of all clinical, electrocardiographic and coronary arteriographic variables was to assess simultaneously the relative contribution of each variable to prediction of overall survival. Two analyses were performed. Because only 68 patients underwent stress electrocardiography, data on all 78 patients were first analyzed without stress electrocardiographic findings. Then data on the 68 patients who had a stress test were separately analyzed. The percent narrowing in each major artery was entered into each multivariate analysis as both a continuous variable (30, 50, 70, for example) and a dichotomous variable with percent narrowing being either 70 percent or greater or less than 70 percent. Because the analysis that used the narrowing as a continuous variable gave a somewhat better prediction for survival, only this analysis is presented.

When all input variables except the stress electrocardiographic findings were considered (78 patients), a combination of three variables was found to be predictive of subsequent death. These were, in order of degree of predictivity: (1) the simultaneous occurrence of narrowing in the right coronary artery and in the left anterior descending artery (either segment 6 or segment 7); (2) history of a myocardial infarction before arteriography; and (3) the presence of a 70 percent or greater narrowing proximal to the first anterior descending septal branch (Table IV). No other variables added significantly to the ability to predict mortality in this analysis.

When the stress electrocardiographic findings were included (68 patients), the variables that were most predictive of subsequent death included: (1) the percent narrowing in the right coronary artery simultaneous with the presence of a 70 percent or greater nar-

TABLE IV

Prediction of Mortality by Multivariate Stepwise Discriminate Function Analysis of all Variables Except Stress Electrocardiography [alive (n = 49); dead (n = 29); total (n = 78)]

Step	Variable Entered	Correctly Predicted Alive	Correctly Predicted Dead	Total Correctly Predicted	p*	Incorrectly Predicted Alive	Incorrectly Predicted Dead
1	RCA × LAD†	27 (55%)	22 (76%)	49 (63%)	<0.001	7	22
2	Prior MI	37 (76%)	22 (76%)	59 (76%)	<0.01	7	12
3	Proximal LAD 70% or greater narrowing	36 (74%)	22 (76%)	58 (74%)	<0.05	7	13

* p significance level of contribution of prediction for each variable. Although each variable does not appreciably alter the percent of correct predictions, the precision of the estimate of the percent is enhanced by the level shown. † Simultaneous narrowings in the right (RCA) and left anterior descending (LAD) coronary arteries. Interaction variable where percent narrowings in both arteries were entered as continuous variables.
MI = myocardial infarction.

rowing proximal to the first anterior descending septal branch; (2) a positive stress electrocardiographic test; (3) history of a myocardial infarction before arteriography; and (4) percent narrowing in the left circumflex artery simultaneous with the presence of a 70 percent or greater narrowing distal to the first anterior descending septal branch (Table V). No other variable in this patient group, including anginal status, electrocardiographic findings at rest, the extent of coronary disease, the presence of collateral vessels to the anterior descending artery, contributed significantly to the prediction of subsequent survival.

In Tables IV and V, the variable shown in step 1 was the best predictor of patients who were alive and those who died. Step 2 shows the variable with the next highest predictive value. The probability (p) values represent statistical significance in achieving this prediction. For convenience, it is helpful to examine the percent correctly predicted at each step. For example, in step 1 in Table V, the simultaneous occurrence of 70 percent or greater narrowing in the proximal left anterior descending artery and in the right coronary artery correctly identified 16 of 24 patients who died whereas the absence of one or both of these variables correctly predicted 33 of 44 patients who were alive at follow-up study. Hence, the outcome of 49 of 68 patients was correctly predicted by the simultaneous presence of these two variables.

Discussion

This study of the natural history of patients with coronary heart disease was prompted by two questions: (1) the relative contribution to survival of the many clinical, electrocardiographic and coronary arteriographic variables available to the physician at the time of cardiologic evaluation; and (2) the mortality, rate of nonfatal infarction and symptomatic status of patients who have not undergone any cardiac revascularization procedure, but who are comparable with persons now considered for coronary bypass surgery. Previous natural history studies have not made suitability for such surgery a criterion for inclusion.

Independent predictors of prognosis: Several investigators[3–5,25] have reported a greater risk of death in patients with significant left anterior descending arterial disease than in those whose disease is limited to either the left circumflex or the right coronary artery or both arteries. Our study confirms this finding. Virtually all of the deaths in our study occurred in patients with disease of the left anterior descending coronary artery. Because significant disease of this artery is very common among symptomatic patients with coronary disease, the presence of a 70 percent or greater narrowing in this vessel did not, by itself, discriminate between those who would live and those who would die. Multivariate analysis of the entire patient group (without

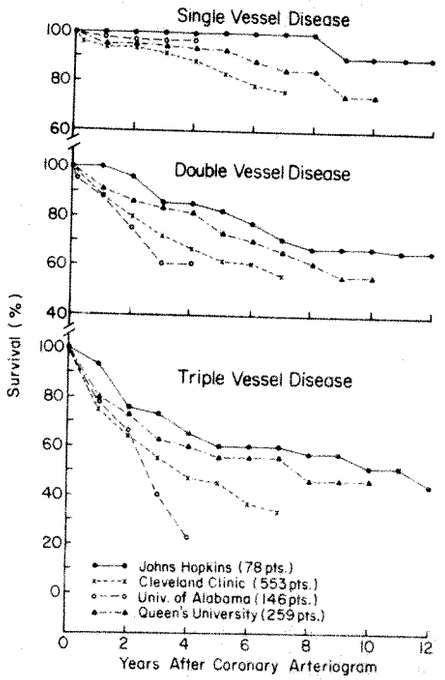

FIGURE 10. Cumulative survival of patients with one, two or three major coronary arteries narrowed by 50 percent or greater. Data from three previous studies[30–32] as well as from this report are included. pts. = patients.

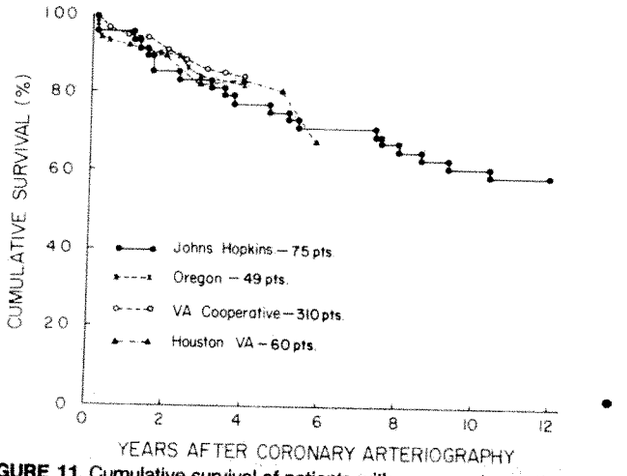

FIGURE 11. Cumulative survival of patients with coronary heart disease who were surgically "suitable" but followed up with medical therapy. Data from three prospective randomized studies of medical versus surgical therapy[27,28,34] as well as from this report are included. pts. = patients.

stress electrocardiographic findings) demonstrated that two anatomic situations independently placed a patient at high risk of dying. The first was the simultaneous narrowing of both the left anterior descending and the right coronary arteries; the second was the presence of a 70 percent or greater narrowing proximal to the first anterior descending septal branch. The only other variable that independently contributed to predicting survival for the entire group was the history of a myocardial infarction before arteriography. When the results of stress electrocardiography were considered, this variable was also found to be a significant independent predictor of survival. Thus, multivariate analysis emphasizes the importance of considering not only clinical and electrocardiographic data at rest in assessing patient prognosis, but also the findings of coronary arteriography and stress electrocardiography.

Prognosis of surgically suitable patients treated medically: The ideal study to determine subsequent survival with medical therapy of patients suitable for coronary bypass grafting is to allocate these patients randomly to either medical or surgical therapy after coronary arteriography. Whereas at least four such prospective studies are currently underway,[26–29] the long-term results will not be known for several years. An alternative approach is to review the natural history of suitable patients who underwent coronary arteriography before the availability of coronary bypass grafting.

"Suitability" for coronary bypass graft surgery was an important criterion for selecting patients included in this natural history study. Thirteen percent of the patients with significant (at least one artery narrowed by 70 percent or more) obstructive coronary disease were excluded from this study because of diffuse distal coronary disease or presumed very poor left ventricular function. A patient who is judged suitable for coronary bypass surgery is likely to have a more favorable prognosis than the patient with more extensive coronary disease or severe left ventricular dysfunction. This may be the reason why survival in our series is better than that reported by three other centers[30–32] (Fig. 10). During the period that the series at Queen's Hospital[32] and the Cleveland Clinic[30] were accumulated, the operation of choice for patients with coronary atherosclerosis was implantation of the internal mammary artery. It is possible that many patients with a more favorable coronary and left ventriculographic anatomy underwent this procedure while the medical treatment group included a higher percent of patients with more extensive coronary or left ventricular disease, or both. Neither of these reports indicates why some patients were referred for surgery and other patients were not. Although implant surgery was not routinely performed at the University of Alabama[31] during the period that the 206 patients in that series underwent arteriography, there was no attempt to exclude patients with diffuse distal coronary disease or very poor left ventricular function who might not be suitable candidates for coronary bypass surgery by current criteria.

The cumulative survival of patients in our series is very comparable with that of the surgically suitable but medically treated patients in the Veterans Administration Cooperative,[33] Houston Veterans Administration[27] and the University of Oregon[28] studies (Fig. 11). When survival of patients with one, two or three vessel disease is examined separately, the cumulative survival of the patient subgroups in our series is similar to that of the Veterans Adminstration Cooperative Study.[33] Although not included in Figure 11, the expected survival of an age-matched patient group drawn from the general population is better than any of the patient groups with coronary heart disease. Expected survival

in a normal 43 year old man for the next 4, 8, and 12 years is 98, 95 and 90 percent, respectively.[34]

Left anterior descending arterial stenosis proximal versus distal to the first septal perforating branch: There are at least two possible reasons why a patient with significant (70 percent or greater) narrowing proximal to the first septal perforating branch may be at a higher risk of mortality. First, narrowing proximal to the first septal perforating branch is very often also proximal to, or involves the origin of, the first diagonal branch of the anterior descending artery. Hence, three sizable myocardial segments including the interventricular septum, the myocardium perfused by the first diagonal branch and the distal main stem left anterior descending artery are jeopardized by a narrowing at this location. A second possible reason for the increased mortality associated with narrowing proximal to the first septal branch relates to the importance of regional ischemia or infarction of the interventricular septum, a situation that may predispose to ventricular arrhythmia and conduction defects. Among our patients who died, 15 of the 19 sudden cardiac deaths in our series were noted in those patients with a significant narrowing proximal to the first septal branch. Further study is needed to understand these two possibilities. Nevertheless, the outcome in the seven patients in our study with single vessel disease involving only the anterior descending artery proximal to the first septal branch was very favorable. Although a 70 percent narrowing of the anterior descending artery at this location was a significant independent predictor of survival, an even more powerful predictor was the simultaneous presence of disease in the right and left anterior descending artery. Thus, two important factors may contribute to survival: (1) narrowing proximal to the first septal branch and (2) significant narrowing in at least one other major coronary artery.

Differences from previous studies: Hammermeister et al.[35] in Seattle and more recently Harris et al.[36] reported follow-up studies that used multivariate discriminate analysis to define predictors of survival in patients treated medically. The findings of these two studies and their approach are very similar to those used in our report. Three important differences between these two studies and ours should be noted. First, the study populations of the Seattle and Duke series are different from that of our series: Both the Seattle and Duke series included patients who were considered for coronary bypass surgery but who did not undergo this procedure. In the Seattle series, the patients treated nonsurgically represented 28 percent of those who entered the registry. In the Duke series, 61 percent of the patients who underwent coronary arteriography were treated nonsurgically for at least 6 months. Ten percent of this "medical" group subsequently underwent coronary bypass surgery and were considered alive but removed from follow-up study at the time of operation. No information is available concerning why these medically treated patients were not referred for surgery although important differences between the medical and surgical cohorts were previously described.[37,38] The second difference between our study and those reported by the Seattle and Duke groups was the availability of ventriculography either to calculate left ventricular ejection fraction or to describe ventricular contraction patterns. The ejection fraction is the best single method to describe left ventricular function, but other variables, including the history of a prior myocardial infarction, electrocardiographic abnormalities at rest, congestive heart failure and heart size on chest X-ray film are indirect measures of left ventricular function and are included in our study. The single most important determinant of ejection fraction in patients with coronary artery disease is the history of a prior infarction. In our study, the history of a prior myocardial infarction was an independent predictor of survival.

The third difference involves the use of slightly different statistical techniques. In describing coronary anatomy, both the Seattle and Duke groups entered the extent of coronary disease as a dichotomous variable divided at the 70 percent or 75 percent level, whereas we used percent narrowing as a continuous variable. Also, we made use of interaction terms to describe disease in two vessels simultaneously or at a specific locus within the left anterior descending artery. Finally, the Seattle and Duke studies described outcome as a 2 or 3 year time-dependent survival rate reflecting variations throughout the study in both time in the study and number of deaths. This procedure appropriately necessitates the use of Cox's hazard function analysis.[39] However, in our long-term follow-up study, all patients were followed up approximately 10 years, and the goal of the multivariate analysis was to predict any death regardless of when it occurred. For this reason, discriminate function analysis treating death as a time-independent process was used.

Clinical implications: This study using multivariate analysis has determined that two arteriographic and two clinical findings independently contribute to patient survival. These are (1) the simultaneous presence of significant disease in both the left anterior descending and right coronary arteries; (2) the presence of a 70 percent or greater narrowing of the left anterior descending artery proximal to the first septal perforator branch; (3) the history of a prior myocardial infarction; and (4) a positive stress electrocardiographic test. Left ventriculography was not performed in these patients. Hence, the influence of left ventricular contraction patterns or ejection fraction on subsequent survival could not be analyzed as separate variables in this group of patients.

Because the pattern of coronary atherosclerosis is an important predictor of survival, one objective of future studies will be to identify by noninvasive methods, such as exercise electrocardiography or thallium-201 myocardial scintigraphy or radionuclide ventriculography, those patients with significant arterial narrowings at these locations.

Merits of Stress Thallium-201 Myocardial Perfusion Imaging In Patients With Inconclusive Exercise Electrocardiograms: Correlation With Coronary Arteriograms

ABDULMASSIH S. ISKANDRIAN, MD, FACC
LOUIS A. WASSERMAN, MD
GARY S. ANDERSON, MD, FACC
HAMID HAKKI, MD
BERNARD L. SEGAL, MD, FACC
SALLY KANE, RN

Philadelphia, Pennsylvania

Stress thallium-201 myocardial perfusion images were obtained in 65 patients with an inconclusive exercise electrocardiogram. All 65 patients underwent coronary angiographic studies. The exercise electrocardiogram was judged inconclusive in 35 patients (54 percent) because submaximal exercise had been performed and in 30 patients (46 percent) who manifested ST-T segment abnormalities at rest. Exercise thallium-201 myocardial perfusion images were abnormal in 20 patients and normal in 45. Nineteen (95 percent) of the 20 patients with abnormal exercise images had severe disease of one or more major coronary arteries. Thirty-seven (82 percent) of the 45 patients with normal exercise images had no significant coronary artery disease; the remaining 8 patients had coronary artery disease. Therefore, 19 of 27 patients with coronary artery disease had abnormal exercise images (sensitivity 70 percent), and 37 of 38 patients without coronary artery disease had normal exercise images (specificity 97 percent). Thallium-201 imaging predicted the correct diagnosis in 56 patients (86 percent). Thus, exercise myocardial imaging with thallium-201 appears to be a useful diagnostic aid in patients with an inconclusive exercise electrocardiogram.

Treadmill exercise testing is widely used as an effective noninvasive diagnostic tool to detect coronary artery disease.[1–5] Several studies have shown a high sensitivity and specificity in preselected patients, particularly those in whom the exercise testing was performed under optimal conditions.[1–4] Exercise test results interpreted as inconclusive or nondiagnostic because of inadequate heart rate response, S-T abnormalities in the electrocardiogram at rest, presence of bundle branch block or a pattern of left ventricular hypertrophy have often been excluded from these reports; therefore, the actual prevalence of inconclusive test results is difficult to ascertain from existing information. A few reports[1,4,6,7] have indicated the occurrence of "indeterminate" or "equivocal" test results in 15 to 30 percent of all patients undergoing treadmill exercise testing.[1,4,6,7]

There is now sufficient reported evidence[6–11] to indicate that exercise thallium-201 myocardial perfusion scintigraphy is an extremely useful procedure in patients suspected of having coronary artery disease. However, only a few studies[7,11] have specifically examined the merits of this procedure in patients with an inconclusive exercise electrocardiogram.

The purposes of this study were (1) to define the incidence of inconclusive exercise treadmill test results, and (2) to evaluate exercise thallium-201 myocardial imaging as a means of detecting coronary artery disease in patients with such test results.

Methods

Patients: For 18 months, 400 patients were studied with a combination of treadmill exercise testing and exercise thallium-201 imaging. In the same period,

From the Likoff Cardiovascular Institute, Hahnemann Medical College and Hospital, Philadelphia, Pennsylvania. Manuscript received December 4, 1979; revised manuscript received March 5, 1980, accepted April 3, 1980.

Address for reprints: Abdulmassih S. Iskandrian, MD, Hahnemann Medical College and Hospital, 230 North Broad Street, Philadelphia, Pennsylvania 19102.

1,174 more patients underwent treadmill exercise testing alone. The exercise electrocardiogram was inconclusive in 146 (36.5 percent) of the 400 patients and in 419 (35.6 percent) of the 1,174 patients. On the recommendation of their physician, 65 of the 146 patients who had undergone both noninvasive procedures underwent cardiac catheterization and coronary arteriography. These 65 patients constitute the group we studied.

Of the 65 patients studied, 40 were men and 25 women (Table I); their average age was 51 years (range 27 to 67). Twenty-six patients (40 percent) had classic angina pectoris, 30 (46 percent) had atypical angina and 9 (14 percent) were asymptomatic and were studied because of a strong family history of coronary artery disease. The resting 12 lead electrocardiogram was normal in 28 patients (43 percent), revealed ST-T wave abnormalities in 33 patients (51 percent) and showed abnormal Q waves indicative of old transmural infarction in 4 patients (6 percent). No patient had electrocardiographic evidence of left ventricular hypertrophy, bundle branch block or preexcitation syndrome, findings that are known to predispose to an inconclusive exercise electrocardiogram.

Treadmill exercise testing: All patients exercised in the fasting state in accordance with a standard Bruce protocol for treadmill exercise testing.[12] Thirty-five patients (58 percent) were receiving propranolol and 12 (18 percent) were receiving cardiac glycosides at the time of the study. Each patient exercised until (1) at least 85 percent of the maximal predicted heart rate for age and condition was reached; or (2) there was 2 mm of downsloping or horizontal S-T segment depression in the absence of a resting S-T abnormality, with or without angina pectoris; or (3) the patient complained of excessive fatigue, leg weakness or shortness of breath; or (4) hypotension, ventricular arrhythmia or dizziness occurred. Three standard electrodardiographic leads (V_1, V_5 and a VF) were continuously monitored. A complete 12 lead electrocardiogram was obtained in each patient immediately after termination of the exercise test.[13]

The exercise electrocardiogram was considered inconclusive in this study when (1) the patient did not achieve 85 percent of the predicted maximal heart rate for age and condition in the absence of diagnostic electrocardiographic changes, or (2) there was S-T segment depression of 0.5 mm or more at rest without an additional 2 mm of S-T depression during exercise.

An exercise treadmill test was considered positive if one or more of the following electrocardiographic criteria were met: (1) 1 mm or greater horizontal or downsloping S-T depression in the absence of a resting S-T abnormality; or (2) 1.5 mm or greater S-T depression 80 ms after the J point, with a slowly rising S-T slope (1 mv/s or less), in the absence of a resting S-T abnormality[14]; or (3) 2 mm of additional horizontal or downsloping S-T depression in the presence of S-T depression in the electrocardiogram at rest.[15] The exercise electrocardiogram was considered negative when the patient achieved 85 percent of the predicted maximal heart rate and there were no ischemic S-T changes. The exercise electrocardiograms were interpreted independently by two observers without knowledge of the results of thallium-201 myocardial perfusion scanning or coronary angiography.

Thallium-201 myocardial imaging: Before these exercise tests were performed, an angiographic catheter was inserted into an antecubital vein and attached to a solution of dextrose in water for flushing. At peak exercise 2 mCi of thallium-201 was injected intravenously and flushed with dextrose and water. The patient was then requested to continue exercising for 30 to 60 seconds more.[16]

Myocardial imaging was performed within 10 to 15 minutes after thallium injection by means of a commercially available scintillation camera equipped with a high resolution parallel hole collimator. Images were obtained in the anterior, 45° left anterior oblique and left lateral projections. Final images were interpreted after background correction (20 to 25 percent) without computer smoothing.

Images were considered normal when there was homogeneous distribution of activity in all segments of the left ventricle. They were considered abnormal when there was partial or complete absence of activity in one or more segments in the known distribution of the coronary arteries.

In patients with abnormal exercise imaging results, redistribution studies were performed in the projection indicating the abnormality 4 hours after the initial study. The images were considered positive when the perfusion defect was seen in the stress study but was absent in the redistribution images, or when the defect in the stress study was larger than that in the redistribution study. Images were interpreted independently by two observers without prior knowledge of the results of exercise electrocardiography or angiography.

Cardiac catheterization and angiography: Each patient underwent left and right heart catheterization in the fasting

CAD = coronary artery disease; ECG = electrocardiogram.

state within 6 months of the exercise studies. Left ventriculography was performed in a 30° right anterior oblique projection or in biplane right and left anterior oblique projections. The contraction pattern was assessed qualitatively for wall motion abnormalities; hypokinesia was defined as reduced motion, akinesia as absence of motion and dyskinesia as a paradoxic systolic bulge. Selective coronary arteriography was performed in multiple projections; when indicated, special cranial and caudal sagittal oblique projections were used.

Significant coronary artery disease was considered present when there was 70 percent or more narrowing in the diameter of one or more of the major coronary arteries (the left main, left anterior descending, left circumflex or right coronary artery) or in one or more of the secondary branches of the left coronary system (marginal or posterolateral branches of the left circumflex artery and diagonal branches of the left anterior descending artery). Collateral channels were considered present when there was delayed opacification of a vessel beyond the site of narrowing or occlusion. The cine films were reviewed independently by two cardiologists without prior knowledge of the results of exercise electrocardiography or thallium imaging.

The consensus of the two observers was used in the analysis of the results of the exercise electrocardiograms and coronary angiograms. There was total agreement between the two observers in the interpretation of the thallium-201 images in 60 of the 65 patients and disagreement on some minor points in 5. The independent interpretation of a third observer was sought in the latter cases and the final determination was made on the basis of agreement of two of the three observers.

Definition of terms: The following definitions are used in the study:

Sensitivity:

$$\frac{\text{True positive}}{\text{True positive + False negative}} \times 100$$

Specificity:

$$\frac{\text{True negative}}{\text{True negative + False positive}} \times 100$$

Predictive positive value:

$$\frac{\text{True positive}}{\text{True positive + False Positive}} \times 100$$

Predictive negative value:

$$\frac{\text{True negative}}{\text{True negative + False negative}} \times 100$$

True positive: Patient with coronary artery disease and an abnormal thallium-201 exercise scan.

True negative: Patient with no coronary artery disease and a normal thallium-201 exercise scan.

False positive: Patient with no coronary artery disease and an abnormal thallium-201 exercise scan.

False negative: Patient with coronary artery disease and a normal thallium-201 exercise scan.

Results

Angiographic findings (Table I): Twenty-seven of the 65 patients had coronary artery disease. In 21 patients, the disease involved one or more of the major coronary arteries: one vessel in 8 patients, two vessels in 8 and three vessels in 5. In the remaining six patients, disease was limited to the secondary branches of the left coronary system. Collateral channels were present in 18 patients (67 percent). The left ventriculogram in patients with coronary artery disease was normal in 9 patients but showed mild hypokinesia in 13 patients and segmental akinesia or dyskinesia in 5 patients. Of the 27 patients with coronary artery disease 20 (74 percent) had typical angina pectoris, 6 (22 percent) had atypical angina and 1 had no angina. The remaining 38 patients had no significant coronary artery disease; of these, only 6 (16 percent) had typical angina, whereas 24 (63 percent) had atypical angina and 8 had no angina.

Electrocardiographic exercise test findings: All 65 patients had an inconclusive exercise electrocardiogram because of submaximal exercise performed or S-T segment abnormalities at rest. None of the patients with S-T abnormalities at rest had an additional 2 mm of horizontal or downsloping S-T depression on exercise. Of the 35 patients whose exercise electrocardiogram was inconclusive because of submaximal stress, 20 (57 percent) were receiving propranolol and 5 (14 percent) were receiving cardiac glycosides; similarly, of the 30 patients whose exercise electrocardiogram was inconclusive because of resting S-T abnormalities, 15 (50 percent) were receiving propranolol and 7 (23 percent) were receiving cardiac glycosides (difference not significant).

Exercise thallium-201 imaging: Twenty of the 65 patients had a positive exercise thallium-201 myocardial imaging result. Of these, 19 (95 percent) had severe coronary artery disease (Fig. 1 to 3). All 20 patients underwent a redistribution study, which showed partial or complete filling of the defects in each patient. Persistent but smaller defects in the delayed images were observed in eight patients; three patients had akinetic or dyskinetic segments, three had hypokinetic segments and two had no wall motion abnormalities. The abnormal exercise images were present in 12 (75 percent) of the 16 patients with an inadequate heart rate response during exercise and in 7 (64 percent) of the 11 patients with resting S-T abnormalities (difference not significant).

Forty-five patients had normal findings on exercise thallium-201 myocardial imaging. Thirty-seven (82 percent) of these patients had either completely normal coronary angiograms (30 patients) or less than 50 per-

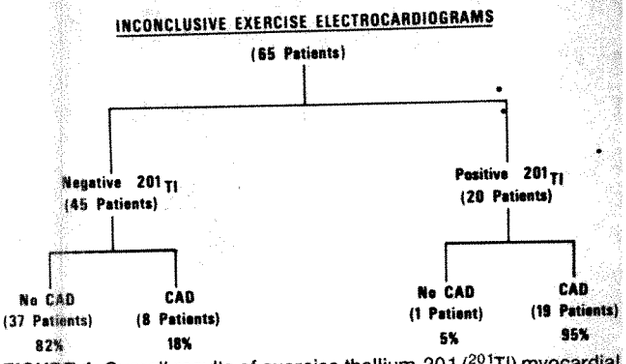

FIGURE 1. Overall results of exercise thallium-201 (^{201}Tl) myocardial perfusion scintigraphy in 65 patients with an inconclusive exercise electrocardiogram. Nineteen of 20 patients with a positive (abnormal) thallium imaging result had coronary artery disease (CAD), and 37 of 45 patients with a negative (normal) thallium imaging results had no coronary artery disease.

cent narrowing of one vessel (7 patients) (Fig. 1). Of the remaining eight patients, six had coronary artery disease limited to the secondary branches of the left coronary system. (In four patients the disease was limited to the marginal branch of the left circumflex artery, and in two there was disease of a marginal branch plus a diagonal branch of the left anterior descending artery.) In contrast, all 19 patients with abnormal exercise images had disease of the major coronary arteries.

These data can be stated in a different way: Only 1 of the 38 patients without coronary artery disease had a positive exercise thallium-201 imaging result (specificity 97 percent). Of the 27 patients with coronary artery disease, 19 had a positive imaging result (sensitivity 70 percent). Thallium-201 imaging predicted the correct diagnosis in 56 (86 percent) of the total group of 65 patients with an inconclusive exercise electrocardiogram; it had a predictive positive value of 95 percent and a predictive negative value of 82 percent.

Comparison of results with those of patients with a conclusive treadmill exercise electrocardiogram: The results are similar to our experience in 123 patients (65 patients with and 58 without coronary artery disease) with a conclusive (either positive or negative) treadmill exercise electrocardiogram (unpublished data). In that series, 52 (80 percent) of the 65 patients with coronary artery disease had abnormal exercise images and 56 (97 percent) of the 58 patients without coronary artery disease had normal exercise images. Of the 52 patients with abnormal exercise images and coronary artery disease 38 (73 percent) manifested perfusion abnormalities at a submaximal exercise heart rate; the exercise electrocardiogram was positive in these patients at a submaximal exercise heart rate. This finding is comparable with the results of the present study, which showed that 12 (75 percent) of 16 patients with coronary artery disease manifested exercise-induced perfusion abnormalities at a submaximal heart rate; however, the exercise electrocardiograms in this latter group of patients failed to show ischemic S-T changes.

Thus, exercise thallium-201 imaging in the patients with a conclusive exercise electrocardiogram had a sensitivity of 80 percent, a specificity of 97 percent and an accuracy rate of 88 percent. In the total group of 123 patients, the exercise electrocardiogram was positive in 48 (74 percent) of the 65 patients with coronary artery disease and negative in 50 (86 percent) of the 58 patients without such disease. The exercise electrocardiogram in the 123 patients had a sensitivity of 74 percent, a specificity of 86 percent and an accuracy rate of 80 percent.

Discussion

Causes of inconclusive treadmill exercise tests: Our findings suggest that treadmill exercise test results are inconclusive in 36 percent of all such tests performed at our institution. The two most common reasons were inadequate heart rate response (54 percent) (Fig. 2) and the presence of S-T depression in the electrocardiogram at rest (46 percent) (Fig. 3).

Although S-T depression on exercise that is at least 2 mm greater than that measured at rest has been reported to indicate a possible abnormal response, none of our patients with S-T depression at rest achieved an additional 2 mm of depression on exercise. Various cardiac and noncardiac medications are known to produce S-T depression. Only seven patients with resting S-T depression in our study were receiving cardiac glycosides. Fifty-seven percent of the patients with an

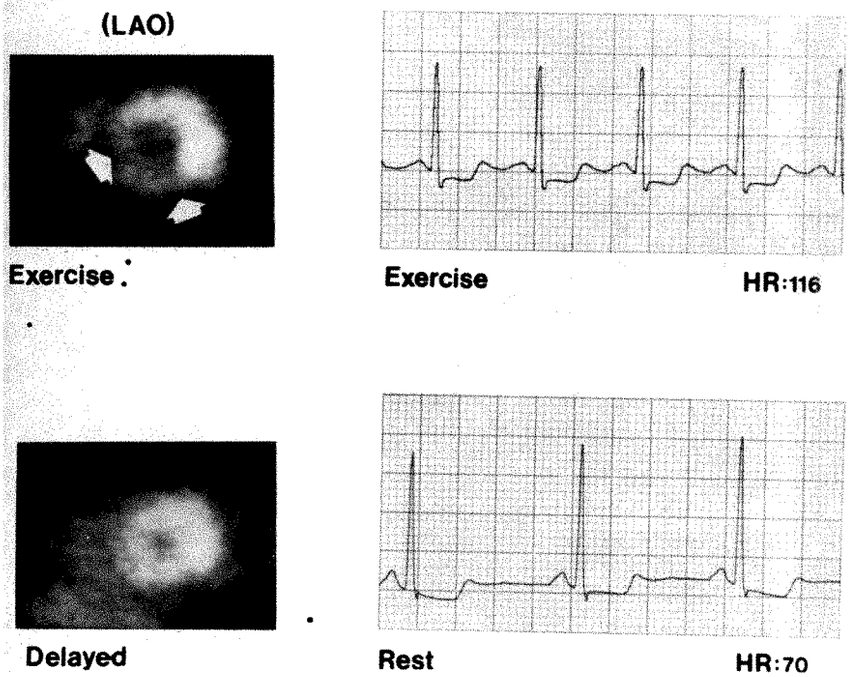

FIGURE 2. Exercise and delayed electrocardiograms and thallium-201 myocardial perfusion scans in a 48 year old woman with chest pain and two vessel coronary artery disease. Electrocardiographic lead V_5 shows S-T segment depression at rest. The exercise electrocardiogram is inconclusive because the maximal heart rate (HR) reached was only 116 beats/min. The target heart rate for this patient was 160 beats/min (85 percent of the predicted maximal rate). The thallium-201 scan shows a perfusion defect in the anteroseptal region (**arrows**) during exercise. LAO = left anterior oblique projection.

inadequate heart rate response were receiving propranolol; however, half of the patients who achieved 85 percent of the maximal predicted heart rate but whose exercise electrocardiogram was inconclusive because of resting S-T depression were also receiving propranolol (difference not significant). The limiting factors in these patients with inadequate heart rate response were leg weakness, general fatigue, shortness of breath and lack of motivation.

Role of exercise thallium-201 myocardial imaging: This procedure was extremely useful in this group of 65 patients with an inconclusive exercise electrocardiogram. Of the 20 patients with abnormal images, 19 had severe coronary artery disease (70 percent or greater narrowing of one or more major coronary arteries) as determined with arteriography. Delayed images obtained in these patients showed persistent but small defects in eight patients. Residual defects were seen in the presence or absence of wall motion abnormalities, finding in agreement with our previous study.[17]

False negative results with myocardial imaging: Of the 45 patients with normal findings on thallium-201 imaging, 37 (82 percent) had normal coronary arteriograms or less than 50 percent narrowing of one vessel. Thus, eight patients with normal exercise thallium-201 images actually had coronary artery disease. Obstruction of the coronary arteries was confined to secondary branches in six of these eight patients. Four patients with narrowing of an isolated marginal (or posterolateral) branch of the left circumflex system and two patients with significant narrowing in a marginal branch and a diagonal branch of the left anterior descending artery. It appears that exercise thallium-201 imaging is not a sensitive detector of coronary artery disease involving secondary branches. We have previously reported[18] that only 33 percent of patients with isolated coronary branch disease had abnormal results on thallium imaging, probably because of a small ischemic area that was beyond the resolution of the scintillation camera.

One of the two remaining patients with normal imaging results and coronary artery disease had triple vessel disease but extensive collateralization. In the other patient, severe narrowing was noted in the mid segment of the right coronary artery.

In the one patient with abnormal findings on exercise thallium-201 myocardial imaging and normal coronary arteriographic results, a diminutive left anterior descending artery was noted (this vessel terminated about halfway down the anterior wall of the left ventricle). On coronary angiography there was an avascular area of the myocardium near the apex, which corresponds to the region of perfusion abnormality in the exercise scan.[19]

Predictive value of exercise myocardial imaging: In our study, exercise thallium-201 scintigraphy had a specificity of 97 percent, a sensitivity of 70 percent, a predictive positive value of 95 percent and a predictive negative value of 82 percent. With this technique, we were able to predict the correct diagnosis in 56 (86 percent) of the 65 patients with an inconclusive exercise electrocardiogram. In such patients exercise thallium-201 imaging appears to be more reliable when the images are abnormal than when they are normal. This conclusion is based on the higher specificity of the test in comparison with its sensitivity. Our results also suggest that the sensitivity and specificity of exercise imaging are similar in patients with a conclusive and an inconclusive exercise electrocardiogram. This finding is in agreement with the results of McCarthy et al.[7] and

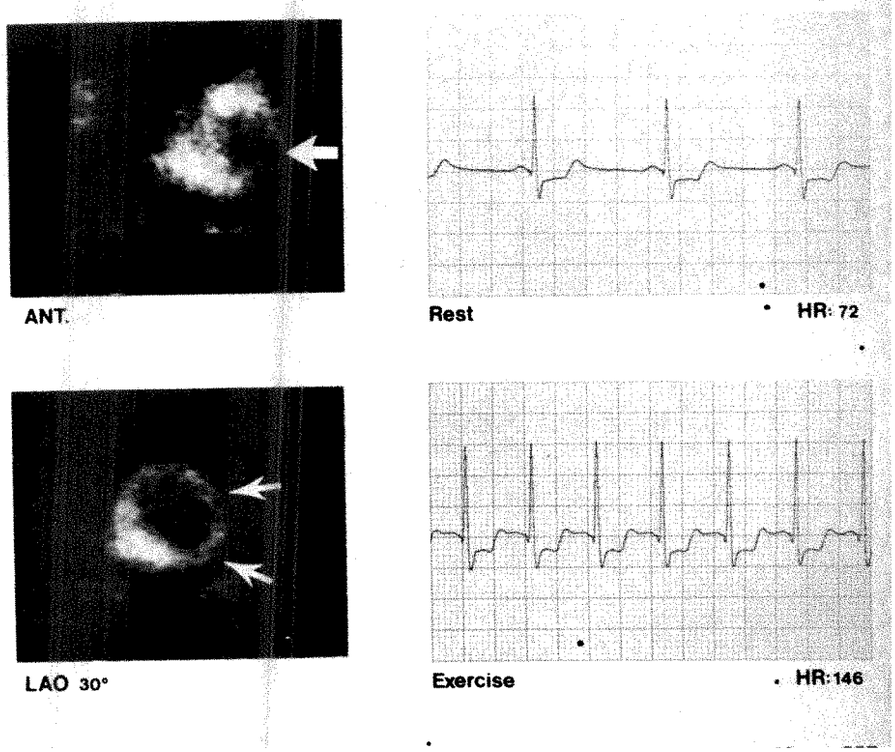

FIGURE 3. Electrocardiograms at rest and during exercise and stress myocardial thallium-201 perfusion scans in a 53 year old man with chest pain and three vessel coronary artery disease. Electrocardiographic lead V_5 shows S-T depression at rest. The exercise electrocardiogram is inconclusive because of the absence of additional 2 mm S-T depression. Myocardial uptake of thallium-201 at peak treadmill stress shows abnormal perfusion in the anterior (ANT) and left anterior oblique (LAO) projections (**arrows**). HR = heart rate (beats/min).

is of interest: Fifty-four percent of the exercise electrocardiograms in our study were inconclusive because only a submaximal work load had been performed.

Our results are important in light of a previous study by McLaughlin et al.,[20] who evaluated 12 patients with coronary artery disease at two levels of exercise. They found that only 16 (53 percent) of 30 ischemic defects present at maximal exercise were evident during light exercise. However, it is not clear from their study how many patients (rather than ischemic defects) did not manifest any ischemic defects on light exercise. Moreover, during experimental production of myocardial ischemia, the electrocardiographic abnormalities appear later than the perfusion, metabolic and wall motion abnormalities. This fact, in combination with variations in the level of "light" exercise, may explain why 12 of our 16 patients with coronary artery disease showed scintigraphic abnormalities during submaximal exercise in the absence of ischemic S-T changes. We concluded, therefore, that light exercise is more likely to underestimate the extent of myocardial ischemia than to detect ischemia.

Although all of our 19 patients with no coronary artery disease had normal exercise images at a submaximal heart rate, we still suggest caution in accepting a negative exercise scan at a suboptimal heart rate as clear evidence of the absence of myocardial ischemia. Further studies are needed to confirm our findings.

The relatively low sensitivity of exercise thallium-201 imaging in this selected population may be related in part to the inclusion of patients with disease in coronary arterial branches. In a previous study,[17] we found that exercise thallium-201 imaging has a sensitivity of 88 percent in patients with 70 percent or greater narrowing of the major coronary vessels. McCarthy et al.[7] also found that exercise thallium-201 imaging is useful in patients with inconclusive exercise electrocardiograms and that the values for sensitivity and specificity of exercise imaging are not statistically different from those of treadmill exercise testing if only the conclusive (positive or negative) results are analyzed. Our experience (unpublished data) supports this conclusion.

Clinical Implications

We believe that thallium-201 imaging is valuable in screening patients with an inconclusive exercise electrocardiogram for coronary heart disease. The high specificity and predictive accuracy of this noninvasive method could reduce the need for coronary arteriography in such patients.

Pathogenesis of Paroxysmal Hypertension Developing During and After Coronary Bypass Surgery: A Study of Hemodynamic and Humoral Factors

RONALD WALLACH, MD, FACC
ROBERT B. KARP, MD, FACC

Birmingham, Alabama

A prospective study of hypertension first appearing during and after saphenous vein bypass coronary surgery was performed in 28 patients to examine the incidence, hemodynamics and mechanism of this problem. In 15 patients (54 percent) new hypertension developed (mean arterial pressure greater than 107 mm Hg), characterized by increased peripheral vascular resistance and unchanged cardiac output within 1 hour after surgery. These 15 patients had a longer history of angina of greater severity, but also had relatively well preserved ventricular myocardium. Because plasma renin activity was depressed in patients in the hypertensive group, activation of the renin-angiotensin system was not important in the pathogenesis of this postoperative hypertension. The expected decrease in total peripheral resistance at the onset of cardiopulmonary bypass was observed in all patients, but later during bypass the peripheral resistance increased in all patients in association with a rise in plasma epinephrine levels. Patients who had hypertension postoperatively had a greater increase in arterial pressure and total peripheral resistance during cardiopulmonary bypass than did those with normal postoperative blood pressure. An elevation in plasma epinephrine and norepinephrine concentration, suggesting enhanced sympathoadrenal responsiveness to the challenge of cardiopulmonary bypass, was characteristic of the hypertensive group. This evidence of enhanced sympathetic activity during surgery may be a useful predictor of the development of postoperative hypertension.

Hypertension after coronary bypass surgery has been characterized by an increase in total peripheral resistance with normal cardiac output.[1,2] Both the renin-angiotensin system[3–5] and the sympathetic nervous system[1,2,4] can cause vasoconstriction and have been suggested as primary mediators of the postoperative increase in total peripheral resistance. The purpose of this prospective study was to establish the incidence of postoperative hypertension in patients undergoing coronary bypass surgery, to determine whether there are useful predictors of this hypertension and to examine the mechanism of postoperative hypertension in relation to hemodynamic changes, the renin-angiotensin axis and the sympathoadrenal system.

Methods

Patients: Twenty-eight patients scheduled for elective coronary bypass surgery were studied. Usual medications including propranolol and nondiuretic antihypertensive drugs were given until the day of operation. Administration of diuretic drugs was discontinued 48 hours before operation. Recognizing the large number of intraoperative and postoperative variables, we made every attempt to standardize care. The same physicians performed surgery (R.B.K.) and anesthesia (J.G.R.) in all patients.

Surgical protocol: Radial arterial and central venous pressure catheters were inserted before anesthesia. After sternotomy, right and left atrial pressures were measured with small polyvinyl catheters that were left in place for at least 12

hours after operation. The cardiopulmonary bypass pump was primed with Normosol R® (1,000 cc) and a solution (1,000 cc) of 5 percent dextrose and 45 percent saline. Reverse saphenous vein bypass surgery was performed under moderate systemic hypothermia during a single period of hypothermic ischemic arrest on cardiopulmonary bypass.

Premedication with diazepam, morphine sulfate and scopolamine was given 1 hour before surgery. Anesthesia was induced with diazepam (0.5 mg/kg) and maintained with a mixture of 50 percent nitrous oxide and 50 percent oxygen, pancuronium (0.1 mg/kg), fentanyl (up to 10 μg/kg) and halothane (0 to 1 percent). Before cardiopulmonary bypass, the halothane dosage was adjusted to maintain the heart rate, systolic pressure and the heart rate-pressure product within 30 percent of control values. During cardiopulmonary bypass, systemic hypotension was not treated unless the mean arterial pressure was persistently less than 50 mm Hg at a pump flow of 2.2 liters/min per m^2. If mean arterial pressure increased to 100 mm Hg at 1.6 liters/min per m^2, then either flow was reduced or halothane was administered. Halothane was not routinely administered during cardiopulmonary bypass. After cardiopulmonary bypass, systolic arterial pressure of less than 80 mm Hg was treated with an intravenous bolus injection of 5 mg of ephedrine or 100 mg of calcium chloride.

Postoperative protocol: After operation, patients were monitored in the cardiac surgery intensive care unit. Respiration was assisted by an intermittent mandatory ventilation volume cycle respirator to maintain normal arterial blood gases. Patients were sedated with morphine sulfate as needed to relieve pain. Care was taken that all patients were adequately sedated and free of remediable respiratory difficulties before a diagnosis of postoperative hypertension was made. The cardiac surgery intensive care unit provided on-line computer measurement and treatment facilities[6] that allowed standardized care for all patients. Blood pressure, left and right atrial pressure, heart rate and body temperature were recorded at 5 minute intervals. Blood or albumin was administered by computer to maintain left atrial pressure at 8 mm Hg in all patients.

Plasma renin activity and catecholamines: Samples of blood for measurement of plasma renin activity, epinephrine, norepinephrine, arterial blood gases, hemoglobin, sodium and potassium were taken (1) before induction of anesthesia, (2) immediately after sternotomy, (3) 5 minutes after the start of cardiopulmonary bypass, (4) before release of the aortic cross clamp near termination of cardiopulmonary bypass, (5) at the time of closure of the sternum, and (6) 1 hour after the patient's arrival in the cardiac surgery intensive care unit, when the first measurement of cardiac index was obtained. Plasma renin activity was measured in all patients with radioimmunoassay techniques,[7] and plasma epinephrine and norepinephrine were measured in the last 21 patients with a modification of the radioenzymatic method of Passon and Peuler.[8]

Hypertension: Hypertensive patients were defined as those in whom a mean arterial pressure greater than 107 mm Hg developed in the cardiac surgery intensive care unit. Patients were observed during the 1st hour without antihypertensive intervention unless blood pressure exceeded 175/110 mm Hg. After 1 hour in the unit, or before antihypertensive therapy was begun, a cardiac index was measured in duplicate using the green dye-dilution technique, with dye flowing from the left atrium to the radial artery.

Statistical analyses: Analyses comparing the hypertensive and nonhypertensive patients at specific time periods were performed using Student's t test and data are reported as mean ± standard error of the mean. Discriminant analysis and linear regression techniques[9] were used to evaluate the predictive value of the following preoperative variables in relation to postoperative hypertension: history of hypertension, use of antihypertensive medication, propranolol therapy, severity of angina (Canadian Heart Association classification), duration of angina, number of saphenous vein bypass grafts inserted, number of previous myocardial infarctions and presence of a normal left ventriculogram. Left ventricular function was evaluated by at least single plane angiography in all patients. Correlation coefficients were determined for mean arterial pressure versus plasma epinephrine, norepinephrine and renin activity.

Results

Fifteen (54 percent) of the 28 patients had a mean arterial pressure greater than 107 mm Hg during the 1st hour in the cardiac surgery intensive care unit, and another patient became hypertensive shortly thereafter. Four of these patients were severely hypertensive (mean arterial pressure greater than 130 mm Hg) soon after arriving in the unit. No patient became hypertensive while in the operating room after cardiopulmonary bypass.

Preoperative measurements: Analysis of preoperative data revealed no significant differences between the postoperatively hypertensive and nonhypertensive patients with regard to age, sex, body surface area or history of myocardial infarction, diabetes mellitus and hypertension (Table I). Preoperative treatments, including administration of antihypertensive medications and propranolol, were similar in the two groups. Patients who became hypertensive postoperatively tended to have a history of more severe angina (class III or IV) than those who were nonhypertensive (11 of 15 versus 3 of 13 patients, $p < 0.06$). Hypertensive patients also tended to have a longer mean duration of angina than those in the nonhypertensive group (45 ± 16 versus 21 ± 7 months), although this difference was not statistically significant.

Normal left ventriculograms were more common in patients in the hypertensive group (9 of 15 versus 3 of 13 patients, $p < 0.05$). The three patients who had significant (greater than 50 percent) left main coronary arterial stenosis were hypertensive postoperatively. Left

TABLE I

Preoperative Clinical Characteristics

	Nonhypertensive Patients	Hypertensive Patients	p Value
Age (yr)	54 ± 2	58 ± 2	NS

History of hypertension (n)	2 of 13	6 of 15	NS
History of myocardial infarction (n)	9 of 13	7 of 15	NS

BSA = body surface area; n = number of patients; NS = not significant; p = probability.

anterior descending coronary arterial stenosis was present in every patient. There was no difference between the two groups regarding single, double or triple vessel disease. In particular, stenoses in the proximal portions of the left anterior descending and the left circumflex arteries occurred in both nonhypertensive and hypertensive patients with equal frequency.

Of all the preoperative factors analyzed, four proved of most value in predicting which patients would have postoperative hypertension: the severity of angina, the duration of angina, the number of saphenous vein bypass grafts and the presence of a normal left ventriculogram. The discriminant function based on these four variables yielded two false positive and two false negative results for a specificity of 83 percent and a sensitivity of 88 percent.

Intraoperative hemodynamic measurements: Before cardiopulmonary bypass, systemic arterial blood pressure was labile. Peak systolic blood pressure occurred with endotracheal intubation; 16 patients had a systolic pressure greater than 160 mm Hg for brief periods (less than 5 minutes). This pressure usually responded to an increased dose of halothane. Hypertension with intubation was not predictive of postoperative hypertension; 7 of 16 patients who had hypertension during endotracheal intubation were not hypertensive postoperatively.

Cardiopulmonary bypass was associated with a profound decrease in systemic arterial pressure in all patients (Fig. 1). Five minutes after the onset of cardiopulmonary bypass, mean arterial pressure and total peripheral resistance were significantly greater in patients who had postoperative hypertension (Fig. 1, Table II). During cardiopulmonary bypass, mean arterial pressure and total peripheral resistance increased in all patients, but to significantly higher levels in the patients with postoperative hypertension ($p < 0.001$). The hypertensive patients had more grafts (four and five saphenous vein grafts) as well as slightly longer aortic cross-clamp and cardiopulmonary bypass times (Table II). Independently, there was no significant correlation between postoperative hypertension and either aortic cross-clamp time or total cardiopulmonary bypass time. The degree of hemodilution (hemoglobin 8.2 g/100 ml) and systemic hypothermia (30 to 31° C) during bypass was similar in both study groups. Immediately after discontinuation of cardiopulmonary bypass, systolic blood pressure increased to greater than 90 mm Hg in all but six patients, who were treated with either an intravenous bolus injection of ephedrine (5 mg) or calcium chloride (0.5 mg/kg). Further supportive measures were not required, and all patients remained normotensive for the duration of the operation.

Immediately before leaving the operating room, the patients with postoperative hypertension had a significantly higher blood pressure level (hypertensive group 119/67 mm Hg, mean 86 versus nonhypertensive group 106/59 mm Hg, mean 76; $p < 0.05$). Right and left atrial pressures, urinary output, amount of crystalloid solution infused, hemoglobin and arterial blood gases were not significantly different in the two groups.

Postoperative hemodynamic measurements: Mean arterial pressures in the two groups were significantly different on the patients' arrival in the cardiac surgery intensive care unit (Fig. 1). Four patients had marked systolic hypertension (greater than 175 mm Hg) soon after arrival in the recovery room, and treatment was initiated immediately after measurement of cardiac index.

Nonhypertensive and hypertensive patients had similar cardiac indexes and stroke volumes but markedly different total peripheral vascular resistances ($p < 0.001$) (Table III). Right and left atrial pressures, temperature (34° C), hemoglobin (12 g/100 ml) and

CI = cardiac index; LAP = left atrial pressure; MAP = mean arterial pressure; NS = not significant; p = probability; SV = stroke volume; TPR = total peripheral resistance = (MAP − right atrial pressure)/CI.

arterial blood gases were similar in the two groups. Atrial pacing was routinely initiated in any patient with a spontaneous sinus rate of less than 80 beats/min. Therefore, analysis of spontaneous heart rate could not be meaningfully performed.

Hypertensive patients were all treated successfully with intravenous nitroprusside by computer[10] to maintain mean arterial pressure at 100 mm Hg. The mean duration of therapy was 6 hours, although one patient also required continued antihypertensive medication on the 1st postoperative day. All patients were normotensive without medication for the remainder of their hospitalization. Postoperative enzyme determinations and electrocardiograms did not identify a postoperative myocardial infarction in any patient (serum glutamic oxaloacetic transaminase on postoperative day 1: nonhypertensive patients 53 ± 6 versus hypertensive patients 59 ± 6 IU/liter; difference not significant).

Plasma renin activity and catecholamines: Serial determinations of plasma renin activity revealed that patients who remained normotensive after operation tended to have higher levels throughout the study than did those who had hypertension, but this difference was not statistically significant (Fig. 2). Plasma renin activity increased at the onset of cardiopulmonary bypass in both groups, but this change was statistically significant only in the nonhypertensive group ($p < 0.01$). Plasma renin activity changed very little during cardiopulmonary bypass in most patients, despite the very decreased and nonpulsatile arterial pressure. After cardiopulmonary bypass, plasma renin activity decreased significantly in both groups ($p < 0.05$) and approached prebypass levels.

Plasma epinephrine levels were similar in the periods before cardiopulmonary bypass in both groups of patients (Fig. 3). With the onset of cardiopulmonary bypass, plasma epinephrine increased in both groups, but to a higher level in the hypertensive patients. During bypass, plasma epinephrine levels continued to rise. This was most strikingly observed in one patient whose bypass time was prolonged and whose epinephrine level reached 5,736 pg/ml. After cardiopulmonary bypass, plasma epinephrine levels decreased. After the patients had spent 1 hour in the cardiac surgery intensive care unit, plasma epinephrine levels were significantly higher ($p < 0.001$) than control values before cardiopulmonary bypass in the hypertensive group only. There was no significant difference between plasma epinephrine levels in the two groups at that time.

Plasma norepinephrine levels were significantly different in nonhypertensive and hypertensive groups both during cardiopulmonary bypass and in the cardiac surgery intensive care unit (Fig. 4). Before cardiopulmonary bypass, the two groups had similar levels of plasma norepinephrine. In hypertensive patients, plasma norepinephrine increased ($p < 0.01$) within 5 minutes of onset of cardiopulmonary bypass, whereas there was little change in the nonhypertensive patients. During cardiopulmonary bypass, plasma norepineph-

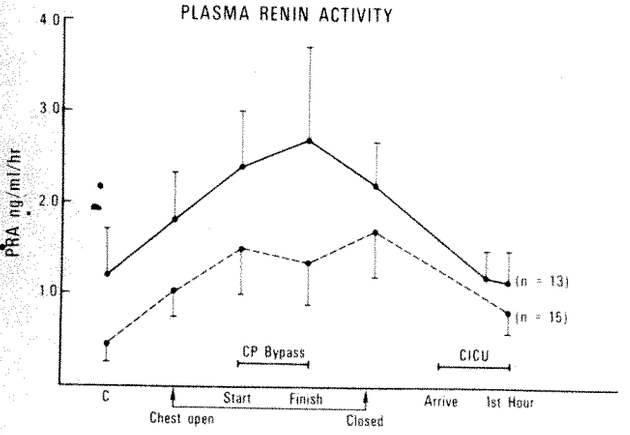

FIGURE 2. Changes in plasma renin activity (PRA) during and after saphenous vein bypass surgery in patients with and without postoperative hypertension. Symbols and abbreviations as in Figure 1.

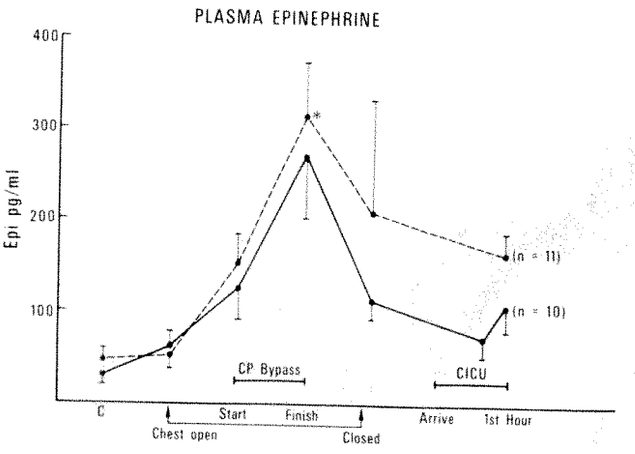

FIGURE 3. Changes in plasma epinephrine (EPi) during and after saphenous vein bypass surgery in patients with and without postoperative hypertension. One patient is excluded (see text). Symbols and abbreviations as in Figure 1.

rine levels decreased or remained unchanged in most patients. Two patients who had postoperative hypertension had a prolonged bypass time and had striking increases in plasma norepinephrine (2,181 and 1,040 pg/ml, respectively) during the bypass period. These patients were excluded from statistical analysis because technical difficulties necessitated the administration of drugs not included in the protocol. At the finish of cardiopulmonary bypass, there was a positive correlation of plasma norepinephrine levels with mean arterial pressure ($r = 0.47$, $p < 0.05$) and of plasma norepinephrine levels with systemic vascular resistance ($r = 0.52$, $p < 0.03$) in all patients studied. After 1 hour in the intensive care unit, plasma norepinephrine in normotensive patients decreased slightly and in hypertensive patients increased by approximately 50 percent, attaining levels higher than control values before cardiopulmonary bypass ($p < 0.01$) and significantly higher than simultaneous levels in the normotensive group ($p < 0.01$). At this time, there was a positive correlation between mean arterial blood pressure and both plasma epinephrine ($r = 0.59$, $p < 0.01$; Fig. 5) and norepinephrine ($r = 0.58$, $p < 0.01$; Fig. 6). There was no correlation between plasma renin and blood pressure.

Discussion

Hypertension developed in more than 50 percent of our patients within 1 hour after saphenous vein bypass surgery. The incidence and time of onset of this hypertension are consistent with previous reports.[1,2,4,11,12] Hemodynamic studies confirmed that both systolic and diastolic blood pressures were increased in these patients. Cardiac index remained unchanged and therefore calculated total peripheral resistance was increased. Circulating epinephrine and norepinephrine levels were elevated in the hypertensive patients, suggesting enhanced activity of the sympathetic nervous system. Postoperative hypertension required treatment for only a few hours after surgery, and most patients remained normotensive thereafter.

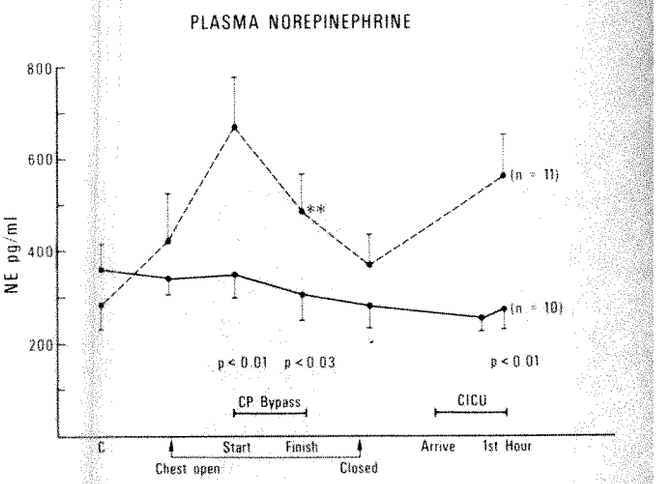

FIGURE 4. Changes in plasma norepinephrine (NE) during and after saphenous vein bypass surgery in patients with and without postoperative hypertension. One patient is excluded (see text). Symbols and abbreviations as in Figure 1.

Preoperative predictive factors: Four factors appeared to be useful in predicting which patients were more likely to have hypertension in the period immediately after coronary bypass surgery: the severity of preoperative angina and its duration, the number of saphenous vein grafts needed and the presence of a normal left ventriculogram. Our observations suggest that patients with severe angina of prolonged duration but with well preserved ventricular myocardium and coronary anatomy suitable for multiple (more than three) saphenous vein bypass grafts tend to become hypertensive postoperatively. We did not find that preoperative hypertension correlated with postopera-

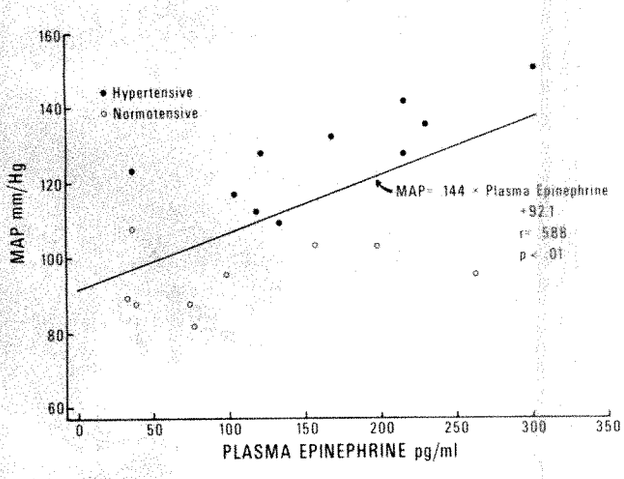

FIGURE 5. Regression analysis comparing mean arterial pressure (MAP) with plasma epinephrine concentration for all patients studied after 1 hour in the intensive care unit. p = probability; r = correlation coefficient.

tive elevation of blood pressure, and this observation is consistent with a previous report.[11] Although other investigators[4] linked preoperative hypertension, particularly when associated with left main coronary artery disease, with an increased incidence of postoperative hypertension, they found no correlation between the latter and severity of angina, left ventricular contraction abnormalities or the number of coronary arterial bypass grafts.

Relation between hemodynamic and humoral factors: The relation between the hemodynamic and humoral changes observed during cardiopulmonary bypass and the emergence of hypertension after saphenous vein bypass surgery is not well defined. Our study demonstrates that patients who have hypertension after saphenous vein bypass surgery respond to cardiopulmonary bypass differently from nonhypertensive patients. A sharp decrease in systemic arterial blood pressure with the onset of cardiopulmonary bypass is expected[13] and occurred in all of our patients. However, the patients who had hypertension postoperatively had higher values for mean arterial pressure and total peripheral resistance than did the nonhypertensive group at the onset of cardiopulmonary bypass. After 5 minutes of bypass, patients who subsequently had postoperative hypertension had an elevated plasma norepinephrine level, whereas in normotensive patients the plasma norepinephrine level was unchanged. In contrast, plasma epinephrine increased to a similar extent with the onset of cardiopulmonary bypass in both hypertensive and nonhypertensive patients. The data suggest increased sympathoadrenal responsiveness to the challenge of cardiopulmonary bypass in the hypertensive group. This index of enhanced sympathetic activity in the hypertensive group may provide a prognostic sign for the development of postoperative hypertension.

Role of plasma renin activity and activation of renin-angiotensin system: A modest increase in plasma renin activity was observed in both hypertensive and nonhypertensive patients after 5 minutes on cardiopulmonary bypass. There was little change in renin levels in either group during the subsequent course of bypass. This finding and the observation that plasma renin activity was greater in nonhypertensive than in hypertensive patients throughout the study are not compatible with the notion that the increased total peripheral resistance observed during cardiopulmonary bypass in patients with postoperative hypertension might be due to activation of the renin-angiotensin system. In addition, there was no correlation between postoperative blood pressure and plasma renin levels. These data do not permit us to relate postoperative hypertension to enhanced activity of the renin-angiotensin system. Other investigators have reported that plasma renin activity decreased[14] or that angiotensin II was increased[3] at the onset of cardiopulmonary bypass. Comparison between our study and these reports is difficult because of differences in cardiac diagnosis of the patients, variable use of hypothermia and normothermia with cardiopulmonary bypass and major differences in anesthetic technique, including premedication with large dose steroids. Previous studies[3–5] further suggested that the renin-angiotensin system is an important mediator of the increased vascular resistance observed in patients with postoperative hypertension. The apparent inconsistency between these studies and our study may be related to their inclusion of patients with valvular heart disease, whose volume status[15] and hemodynamic performance may be different from those of patients with ischemic heart disease. Volume repletion by a computer-controlled system in our study may also have contributed to the absence of higher postoperative renin levels.

Plasma norepinephrine levels and activation of the sympathetic nervous system: The finding that plasma norepinephrine levels were increased significantly after operation in the hypertensive but not in the nonhypertensive patients suggests that the sympathetic nervous system may be a mediator of postoperative hypertension. Plasma epinephrine levels tended to be higher in hypertensive than in nonhypertensive patients after operation, but the difference between groups was not statistically significant. Only in the hypertensive group were plasma epinephrine levels significantly elevated above the levels before cardiopulmonary bypass. However, the postoperative mean arterial pressure correlated with both plasma norepinephrine and epinephrine levels. These findings confirm the observations of Roberts et al.[4] and Fouad et al.,[12] who previously suggested that the hypertension that follows coronary bypass surgery may be related to activation of the sympathetic nervous system.

Role and mechanism of increased sympathetic activity: The pathophysiologic mechanism of increased sympathetic activity in patients who have hypertension after saphenous vein bypass surgery is uncertain. The cardiogenic hypertensive chemoreflex described by James et al.[16] offers the attractive hypothesis that platelet aggregates on coronary atherosclerotic plaques in the proximal left coronary arterial system could release serotonin and trigger a hypertensive response. However, analysis of coronary arteriograms in our study revealed no differences in the incidence of proximal left coronary disease in the hypertensive and nonhypertensive patients. Spinal sympathetic reflexes arising from coronary arterial receptors as demonstrated by Brown and Malliani[17] provide an alternative hypothesis. Chronic hypovolemia associated with ischemic heart disease[15,18] may link the vasomotor instability and increased sympathetic nerve activity observed in postoperatively hypertensive patients. Our study suggests that increases in catecholamines and total peripheral resistance during cardiopulmonary bypass presage similar postoperative responses in the hypertensive group. This increased sympathetic response may be more common in patients with severe, long-standing angina and well preserved left ventricular function. The pathophysiologic role of the sympathetic nervous system in the control of blood pressure during and after saphenous vein bypass surgery deserves further investigation.

The Starr-Edwards model 6400/10 mitral and 2400/10 aortic valve prostheses incorporate metallic tracks on the inner aspects of cloth-covered struts in an attempt to preserve the favorable thromboembolic performance of cloth-covered valves while avoiding the risk of cloth wear. Two hundred seventy operative survivors of mitral valve replacement with the model 6400/10 prosthesis, all on continuous anticoagulant therapy, have been followed up for a mean period of 2.3 (maximal 6) years. The late survival rate is 91 percent and the removal-free rate is 94 percent at 5 years. The rate of embolism (mean ± standard error of the mean) is 4.6 ± 0.9 percent per patient-year. Significant bleeding complications occurred at a rate of 1.0 ± 0.2 percent per patient-year; there were no deaths.

Two hundred forty operative survivors of aortic valve replacement with a model 2400/10 prosthesis, all on continuous anticoagulant therapy, have been followed up for a mean of 2.0 (maximal 7) years. The 5 year survival rate is 84 percent and the removal-free rate is 98 percent. Embolism occurred at a rate of 3.3 ± 0.8 percent per patient-year. Hemorrhagic complications occurred at a rate of 2.1 ± 0.6 percent per patient-year; there were three fatalities.

Cloth wear and hemolysis have not been significant problems with this prosthesis, and the rates of thromboembolism are comparable with those reported for xenograft bioprostheses. The composite strut (track) valve prosthesis is a durable alternative to tissue valves in patients who are able to tolerate anticoagulant therapy.

The Starr-Edwards model 6400/10 mitral (Fig. 1) and 2400/10 aortic (Fig. 2) valve prostheses, introduced in 1972, are the most recent additions to a series of caged ball prostheses that date to the earliest days of cardiac valve replacement. They represent an attempt to preserve the favorable thromboembolic performance of cloth-covered valves while avoiding the risk of cloth wear. This report reviews our experience with these prostheses since 1972.

Methods

Patients: From April 1972 to October 1979, a total of 282 model 6400/10 mitral valve prostheses and 350 model 2400/10 aortic valve prostheses were implanted at the University or Oregon Health Sciences Center, Portland, Oregon; the Tucson Medical Center, Tucson, Arizona; and Mercy Hospital, San Diego, California. These prostheses incorporate metallic tracks on the inner aspects of their cloth-covered struts. The ball is composed of hollow Stellite®. In the current configuration, the orifice cloth is a lock-stitch run-resistant Dacron® fabric protected by metallic studs to eliminate the potential for orifice cloth wear.

The clinical characteristics of the patients discharged on anticoagulant therapy are listed in Table I. All patients underwent replacement of a single valve, although other concomitant procedures were common. Since 1974, valve selection has primarily been based on size, the track valve being reserved for patients with a larger valve orifice (equal to or greater than 30 mm mitral or 25 mm aortic). Before 1978, most replacements were accomplished using cardiopulmonary bypass with moderate systemic hypothermia (30° C), supplemented

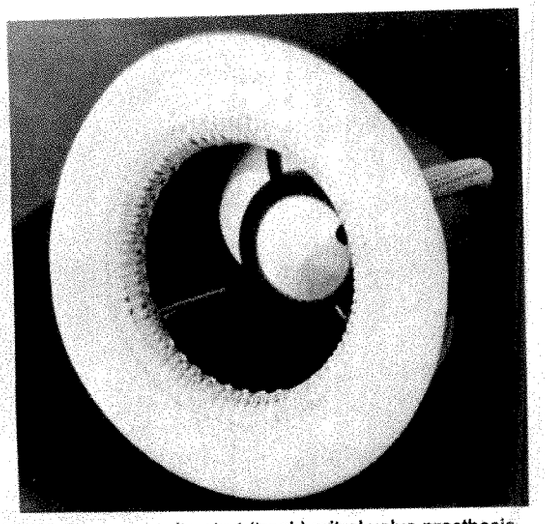

FIGURE 1. The composite strut (track) mitral valve prosthesis.

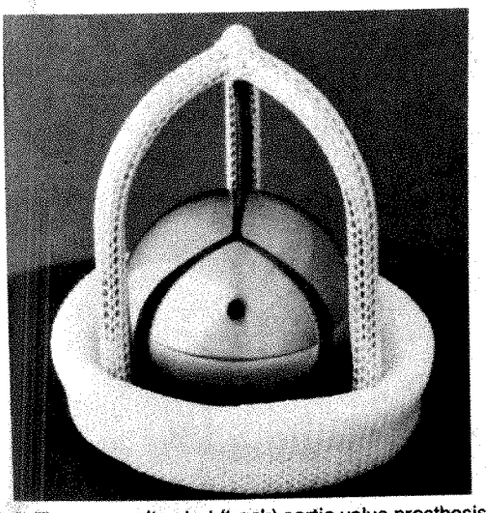

FIGURE 2. The composite strut (track) aortic valve prosthesis.

with continuous coronary perfusion for aortic valve replacement. Recently, systemic hypothermia (30° C) with cold potassium cardioplegia (4° C) has been used.

Follow-up: The patients were followed up with yearly questionnaires; telephone contact was used when questionnaires were not returned or when a complication was suspected. Seventy-four percent of patients with model 6400/10 and 84 percent of patients with model 2400/10 were accounted for during the 18 month period ending in October 1979, reflecting in part a highly mobile patient population from three disparate medical centers. The actuarial method was used to compute survival and embolism-free curves.[1]

Results

Aortic valve replacement: Twenty-three (7 percent) of 350 patients died from events causally or temporally (less than 30 days) related to valve replacement with the model 2400/10 aortic prosthesis. Two hundred forty patients were discharged on continuous anticoagulant therapy. Four of 25 late deaths (16 percent) were valve-related (Table II). The survival rate at 5 years (mean ± standard error of the mean) is 84 ± 3.3 percent (Fig. 3).

TABLE I

Clinical Features of Patients Undergoing Valve Replacement With the Track Valve Prosthesis

	Aortic	Mitral
Operative survivors (n)	240	270
Male/female ratio	6:1	2:3
Mean age (yr)	57.8	54.6
Mean valve size (mm)	25	30
Associated procedures (%)		
Aortocoronary bypass	33	15
Valve reparative	2	9
Total follow-up (patient-yr)	515	613
Follow-up (yr)		
Mean	2.0	2.3
Maximal	7	6

Five aortic valve prostheses required replacement during the follow-up period, all during the 1st year. Three prostheses were removed for prosthetic infection and two for perivalvular leak. The removal-free rate was 98 ± 1 percent at 5 years.

There were 17 instances of embolism (3 fatal, 10 with residual neurologic deficit, 4 transient) in 14 patients. The rates of embolism were 3.3 ±0.8 percent per patient-year for all emboli and 2.5 ± 0.7 percent per patient-year for serious emboli (Fig. 4). Hemorrhagic complications (gastrointestinal, cerebral or hemarthrosis) occurred at a rate of 2.1 ± 0.6 percent per patient-year; there were three deaths.

Mitral valve replacement: Twelve (4 percent) of 282 patients undergoing mitral valve replacement died from events causally or temporally (less than 30 days) related to surgery. One (7 percent) of 15 late deaths was valve-related (Table II). The late survival rate at 5 years is 91 ± 3 percent (Fig. 3).

Four mitral valve prostheses required replacement, two for prosthetic infection, one for thrombotic stenosis and one for recurrent embolism. The removal-free rate at 5 years is 94 ± 3 percent.

There were 28 thromboembolic events (none fatal, 13 residual, 15 transient) in 26 patients for a rate of embolism of 4.6 ± 0.9 percent per patient-year for all emboli and 2.1 ± 0.6 percent per patient-year for serious

emboli. The actuarial embolus-free rate at 5 years is 88 ± 2 percent (Fig. 4). All patients were on continuous anticoagulant therapy. Significant bleeding complications occurred at a rate of 1.0 ± 0.2 percent per patient-year; there were no deaths.

Discussion

The first clinically successful cardiac valve prostheses were of caged ball design. The efficacy and durability of these prostheses have been documented up to 15 years after implantation.[2] The major drawback to these and all other valve prostheses developed to date has been the formation of thrombus on the valve, with a significant incidence of peripheral embolization. Modifications of the original ball valve prosthesis, as well as the introduction of other prostheses of different design, have not been totally successful in eliminating the problem. The introduction of cloth covering of the orifice and struts effected a significant decrease in the incidence of thromboembolism.[3,4] However, cloth tear leading to hemolysis or embolism dampened enthusiasm for this innovation, particularly when the prosthesis was in the aortic position where the cloth was subjected to greater shear forces.

Role of anticoagulant therapy: The Starr-Edwards composite strut (track) prostheses were designed to retain the proved effectiveness and durability of the caged ball prosthesis while minimizing problems related to thromboembolism and cloth wear. We had initially hoped that this design modification would also eliminate the necessity for continuous anticoagulant therapy. However, this latter goal was not realized, because it soon became obvious that patients who did not receive anticoagulant therapy experienced greater morbidity and mortality.[5] We therefore recommend that all patients with ball valve prostheses, regardless of design, receive continuous anticoagulant therapy in the absence of an overriding contraindication. Anticoagulation can be stopped with low risk for brief periods of time in the event of major trauma or surgery.

Incidence of thromboembolism: Has the composite strut prosthesis maintained the thromboembolic protection of cloth covering while eliminating the risk of cloth wear? Embolus-free curves of patients undergoing mitral and aortic valve replacement at this institution with totally cloth-covered (models 6310/20 and 2310/20) and composite strut valve prostheses are presented in Figures 5 and 6. Although occupying different time frames, the groups are roughly comparable in major clinical variables. From these data, it can be seen that the rate of embolism with the track valve prosthesis is nearly identical to that of the totally cloth-covered prosthesis. Moreover, hemolysis and cloth wear have not been a problem to date with the track valve.

Role of track valve prosthesis versus xenograft valve: What should be the current role of the track valve prosthesis? Randomized studies of current cardiac prostheses have not been performed, and the hazards of interinstitutional comparisons are well known. These include differences in patient populations and patient selection and nonuniform long-term postoperative management of anticoagulant therapy by a variety of

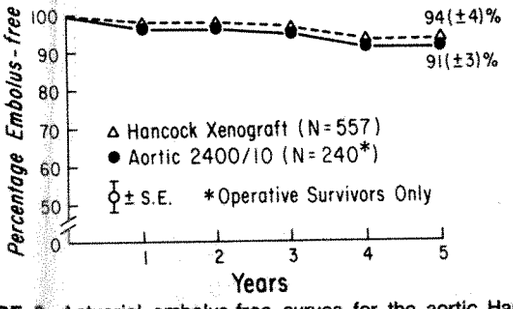

FIGURE 8. Actuarial embolus-free curves for the aortic Hancock xenograft and the composite strut valves.

clinicians. However, comparison with the data of Oyer et al.[6] at Stanford, who used Hancock porcine xenografts exclusively in a clinically comparable group of patients during the same period of time, shows no significant difference in thromboembolic performance (Fig. 7 and 8). One third of their mitral xenograft recipients received long-term anticoagulant therapy. Sudden catastrophic thrombosis in patients on anticoagulant therapy, which is a major problem with the tilting disc valve and could conceivably have accounted for sudden death of unknown cause in their series, has not been seen by us nor previously reported.

Role of valve size: In our selection of the proper valve for a particular patient, some consideration is given to valve size. Although the mean gradient across the 23 mm size valve is in the range of 20 mm Hg, higher gradients are occasionally seen, perhaps related to the accumulation of fibrin on the cloth-covered orifice. Hemodynamic studies in patients with large valves have been more uniformly satisfactory.[7] We therefore currently prefer track valves in sizes 30 mm (mitral) and 25 mm (aortic) or larger. In addition, patients who are thought unable to comply with a regimen of long-term anticoagulant therapy are not considered candidates for mechanical valves. The sound of the track valve is variable, but may be disturbing to some patients. A recent review of experience with the Silastic ball valve in the 1970's described elsewhere[8] demonstrates no significant difference in the 5 year rates of thromboembolism in comparison with other contemporary prostheses, including the track valve. Therefore, we choose the noncloth-covered valve, even in larger sizes, for patients who, in their judgment or that of the clinician, might be unduly bothered by prosthetic noise.

In summary, the composite strut valve offers satisfactory thromboembolic performance and a durable alternative to the glutaraldehyde-preserved porcine xenograft valve in patients who are able to tolerate anticoagulant therapy. We continue to use both the noncloth-covered and track prostheses.

Genesis of Pericardial Knock in Constrictive Pericarditis

THEODORE I. TYBERG, MD
ALLAN V. N. GOODYER, MD, FACC
RENE A. LANGOU, MD, FACC

New Haven, Connecticut

A pericardial knock is a common finding in constrictive pericarditis. However, its origin has been uncertain. One hypothesis suggests that it is due to sudden deceleration of ventricular filling. To validate this hypothesis, left ventriculograms, phonocardiograms and external pulse recordings were obtained in seven patients with hemodynamic and pathologic findings of constrictive pericarditis and in seven normal subjects. Left ventriculographic silhouettes were digitized and left ventricular volumes were calculated by computer at 16 ms intervals. Curves of left ventricular volume versus diastolic filling time were constructed for each patient. Pericardial knock was recognized as an early high frequency sound recorded between 90 to 120 ms after the aortic closing sound and occurring at the trough of the *Y* descent of the jugular venous pressure tracing. The timing of the pericardial knock in five patients with constrictive pericarditis corresponded to a sudden and premature plateau of the diastolic left ventricular volume curve representing 85 ± 4 percent (mean ± standard deviation) of ventricular filling. The diastolic plateau was missing in two patients with constrictive pericarditis who had no pericardial knock. In these cases, the rate of ventricular filling was faster than normal in the first 20 percent of diastole.

Thus, this study related pericardial knock to an abrupt plateau in the diastolic left ventricular volume curve, supporting the view that sudden cessation of ventricular filling generates the pericardial knock of constrictive pericarditis. Two mechanisms are proposed by which the filling plateau may produce the knock, and it is postulated that both ventricles may participate in the knock phenomenon.

Since the first case of constrictive pericarditis was described by Chevers[1] of Guy's Hospital in 1842, the pathophysiologic basis of a high frequency early diastolic sound in this disease has intrigued investigators and clinicians alike.[2] This extra sound has been termed a pericardial protodiastolic sound to distinguish it from the third heart sound or protodiastolic gallop; lately it has been called the "pericardial knock." This sound usually occurs about 90 to 120 ms after the aortic component of the second heart sound, whereas the third heart sound occurs somewhat later (130 to 160 ms). Furthermore, the pericardial knock has a higher acoustic frequency and intensity than the third heart sound.[3]

It has been assumed that the knock is related to sudden cessation of diastolic ventricular filling when the expanding ventricles achieve the limits imposed by a nondistensible, thickened, fibrous or calcified pericardium. This assumption was based primarily on indirect experimental evidence, that is, radiology,[4–6] roentgenkymography,[7] apexcardiography[8] and interpretations of simultaneous right atrial and right ventricular pressure recordings and phonocardiographic studies.[9] In more recent and sophisticated studies, several investigators[10–12] constructed pressure-volume curves for patients with constrictive pericarditis and showed a steep sudden increase in pressure-volume ratios early in diastole. However, these authors did not correlate their pressure-volume findings with phonocardiographic data.

From the Department of Internal Medicine, Cardiology Section, Yale University School of Medicine, New Haven, Connecticut. Manuscript received February 19, 1980; revised manuscript received April 14, 1980, accepted April 18, 1980.

Although these observations suggest that the knock is associated with abrupt changes in ventricular pressure or filling rate, no study has correlated objective measurements of ventricular filling with the knock, and several alternative explanations have been proposed, including the theory that the knock is equivalent to an early third sound gallop in the presence of rapid ventricular filling.[13] This study was therefore undertaken to validate further the hypothesis that a pericardial knock corresponds to a rapid and sudden deceleration of ventricular filling by the constricting pericardium.

Methods

Seven patients with proved constrictive pericarditis and seven normal subjects who had phonocardiograms, external pulse recordings and electrocardiograms taken just before routine cardiac catheterization were studied.

Noninvasive studies. Phonocardiograms, external pulse recordings and electrocardiograms were simultaneously obtained. All patients had their cardiac medications discontinued at least 12 hours before the study. Graphic recordings were obtained with a multichannel fluid-jet recorder (Mingograf 34, Elema-Schoenander, Siemans Company, Iselin, New Jersey) with the patients in the supine position in a noise-insulated room. Phonocardiograms were recorded using standard 50, 100 and 200 hertz filters, and a high impedance microphone (EMT 25C). External pulse recordings were performed using an Elema-Schoenander EMT 510C pulse recorder and a Marey transducer. This system was able to record frequencies as low as 0.2 hertz. Electrocardiographic lead II or III was simultaneously recorded for timing purposes, and all graphic tracings were inscribed on paper at 100 mm/s. Therefore, it was possible to measure accurately time intervals as short as 10 ms.

A *pericardial knock* was recognized as a high frequency diastolic sound recorded between 90 to 120 ms after the aortic closing sound, and occurring at the trough of the Y descent in the jugular venous pulse tracings.

Cardiac catheterization: This procedure was performed with the patients in the postabsorptive state after mild sedation with orally administered diazepam (5 to 10 mg). Right and left heart pressures were measured through fluid-filled catheters connected to Statham $P_{23}Db$ transducers and recorded on an Electronics for Medicine DR-8 recorder. Cardiac output was determined with the Fick method. Left ventricular cineangiography was then performed in the 30° right anterior oblique protection using a conventional 9 inch (22.8 cm) image intensifier and filmed at 60 frames/s.

Silhouettes of the left ventriculogram were traced from a Vangard projector (Vangard Instrument Corporation, Melville, New York) at 16 ms intervals between end-systole and end-diastole. These silhouettes included papillary muscles and trabeculations. The coordinates of these left ventricular silhouette outlines were digitized and volumes were calculated by direct integration, using a Varian 620-i minicomputer (Varian 620-i, Varian Data Machines, Irvine, California). This method divides the left ventricle into cylindrical slices, 1 mm thick, that are summed to give total volume using a modification of Simpson's rule.[14] No correction for rotation or distortion was used, but a correction factor for angiographic magnification was included in the computation. Left ventricular volumes calculated by this angiographic method were reproducible within 4 ± 1 percent in consecutive sinus beats. The left ventricular ejection fraction was also calculated by this method and has been shown to correlate well with ejection fraction calculated with nuclear angiography.[15]

Left ventricular filling volumes were expressed as percents of total filling volume (defined as end-diastolic minus end-systolic volume). The left ventricular end-diastolic silhouette was the largest silhouette preceding the onset of contraction (mitral valve closure). The left ventricular end-systolic silhouette was the smallest silhouette during contraction; this usually coincided with aortic valve closure. Left ventricular diastole was defined as the time from the smallest to the largest left ventricular cavity size before the onset of con-

traction, and expressed as percent duration of diastole. Left ventricular filling curves were constructed for all patients included in this study.

Noninvasive and invasive studies: The purpose of this study would have best been served by simultaneous graphic recordings and left ventriculograms. However, the noise generated by the radiologic equipment made simultaneous recordings impossible. Fortunately, the heart rates of each patient were similar at the times when the phonocardiogram and left ventriculogram were obtained. To minimize further any error induced by this methodologic problem, all phonocardiographic and angiographic data were also expressed in percent of total duration of left ventricular diastole.

Patients: *Constrictive pericarditis:* Of the seven patients with constrictive pericarditis, four were men and three women. The mean age was 45 ± 7 years (mean ± standard deviation). The cause of the pericarditis, symptoms, signs and fluoroscopic findings in these seven patients are presented in Table I. Only five patients had an audible and recorded pericardial knock.

Cardiac catheterization data from these seven patients with constrictive pericarditis are displayed in Table II. All seven patients had sinus rhythm and a prominent *X* and *Y* descent in the right atrial pressure tracings; all had diastolic pressure equilibration in all intracardiac chambers and a "square root" sign in both the right and the left ventricular pressure tracing. Left ventricular angiography (Table III) revealed that six patients had totally normal left ventricular wall motion, and one patient had a hypokinetic anterior wall. End-diastolic left ventricular volumes in the seven patients averaged 102 ± 8 cc and the ejection fraction averaged 58 ± 3 percent.

All seven patients with constrictive pericarditis underwent pericardial stripping. Operative and pathologic notes were reviewed for the degree and location of pericardial fibrosis and for calcium deposition (Table IV).

Normal subjects: Seven patients underwent cardiac catheterization for evaluation of atypical chest pain. They served as a control group, having demonstrated normal findings on physical examination, electrocardiography, hemodynamic study, left ventriculography and coronary arteriography. End-diastolic volume in this control group averaged 138 ± 12 cc (Table III).

Statistical analysis: The two-tailed *t* test for unpaired samples was used to test the significance of observed changes. A probability (p) value of less than 0.05 was considered statistically significant.

Results

Left ventricular diastolic filling curves: In the seven normal subjects (Fig. 1) the composite diastolic filling curve had a rapid slope during the first 10 percent of diastole and a more gradual slope during the remaining 90 percent. At 30 percent of left ventricular diastole, 35 ± 4 percent of left ventricular filling had occurred.

Figure 2 compares the left ventricular diastolic filling curves of the five patients with constrictive pericarditis who had a pericardial knock with the composite filling curve of the normal patients. In constrictive pericarditis there was very rapid early diastolic filling, which reached a plateau at 30 to 40 percent of the duration of diastole. At that point, 85 ± 4 percent (63 to 98 percent) of diastolic filling was achieved as opposed to 35 percent in the control group. Figure 3 compares the diastolic filling curves of two additional patients with proved constrictive pericarditis who did not have a pericardial knock with the composite curve of the normal patients. These two patients had a slightly faster rate of early filling than that of normal subjects, but there was no plateau in the left ventricular filling curve. End-diastolic volume in the patients with constrictive pericarditis was significantly smaller than that in the normal control group (102 ± 8 versus 138 ± 12 cc, $p < 0.05$) (Table III).

* The differences in the phonocardiographic and angiographic timing of the pericardial knock were due to the use of 16 ms angiographic framing intervals.

A-V = atrioventricular; HR = heart rate; LV = left ventricle.

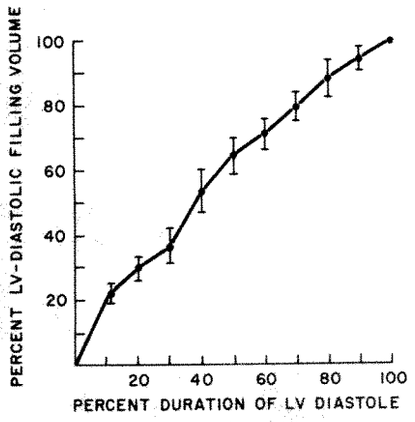

FIGURE 1. Left ventricular (LV) diastolic filling curve in seven normal control subjects, expressed as mean ± standard deviation of the mean.

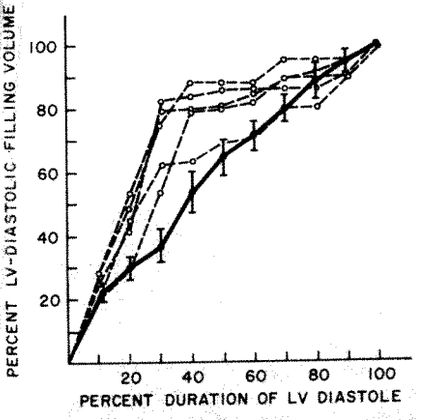

FIGURE 2. Left ventricular (LV) diastolic filling curves in five patients with constrictive pericarditis and a pericardial knock (**open circles and broken lines**) and left ventricular diastolic filling curve in seven normal control subjects, expressed as mean ± standard deviation (**solid circles and solid lines**).

Correlation of pericardial knock and left ventricular filling curve: Figure 4 presents the electrocardiogram, phonocardiogram, jugular venous pulse tracing and left ventricular filling curve in a typical patient with constrictive pericarditis and a knock. The beginning of left ventricular diastole corresponds to the second heart sound (aortic component) and the end of diastole to the first heart sound. The pericardial knock corresponds to the trough of the *Y* descent in the jugular venous tracing and to the beginning of the left ventricular filling curve plateau. Figure 5 presents the electrocardiogram, phonocardiogram, carotid pulse tracing and left ventricular filling curve in a patient with constrictive pericarditis who had no pericardial knock. No plateau in the left ventricular filling curve is evident.

Table IV correlates the phonocardiographic, angiographic and pathologic data in the seven patients with constrictive pericarditis. All patients had sinus rhythm at the time of the study, and their heart rates were similar during the graphic and angiographic studies. The five patients with a pericardial knock demonstrated a sudden plateau in the left ventricular filling curve. The timing of the pericardial knock in the phonocardiogram coincided with the initiation of the left ventricular filling curve plateau in all five patients. The two patients without a pericardial knock manifested no plateau in the left ventricular filling curve. However, they had typical hemodynamic and pathologic

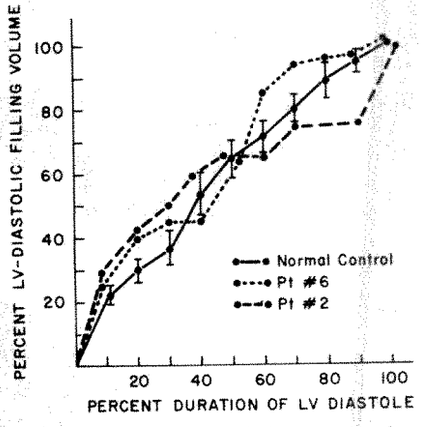

FIGURE 3. Left ventricular (LV) diastolic filling curves in two patients (Pt) with constrictive pericarditis and without a pericardial knock (Patients 2 and 6) (**solid circles and broken lines**) compared with the left ventricular diastolic filling curve in seven normal control subjects expressed as mean ± standard deviation (**solid circles and solid lines**).

findings of constrictive pericarditis, and their clinical condition improved after pericardiectomy.

Discussion

The seven normal control subjects demonstrated a typical pattern of left ventricular diastolic filling that is initially (first 10 percent of diastole) fast and then more gradual and uniform (Fig. 1). This angiographic finding is in agreement with previously reported studies.[16,17]

Pattern of sudden limitation of ventricular filling: The seven patients with constrictive pericarditis revealed two completely different patterns of left ventricular diastolic filling. Filling pattern A was characterized by a rapid filling period that lasted 30 to 40 percent of the total diastolic filling period, followed by a sudden and abrupt plateau. This plateau persisted until the end of diastole, except for a minimal increase in left ventricular filling near end-diastole, related to the atrial contribution to left ventricular end-diastolic volume (Fig. 2). Filling pattern B was characterized by slightly faster than normal filling in the early diastolic filling period (30 percent of diastole), but the curve had an overall shape similar to that of normal subjects (Fig. 3). Table IV discloses that all five patients with constrictive pericarditis and a pericardial knock demonstrated filling pattern A. Furthermore, the beginning of the left ventricular filling curve plateau corresponded temporally to the pericardial knock in each patient. The plateau in the left ventricular filling curve is a graphic representation of an abrupt pathologic cessation of diastolic filling. However, the two patients without a pericardial knock demonstrated filling pattern B. These patients, nevertheless, had the typical hemodynamics of pericardial constriction: elevated diastolic cardiac pressures and square root sign in the right and left ventricular pressure tracings. The angiograms were also characteristic of pericardial constriction: small left ventricular end-diastolic volume, normal left ventricular wall motion and normal left ventricular ejection fraction. They had operatively proved constrictive pericarditis (Table IV) and clinical improvement after pericardiectomy.

Causes for lack of abnormal filling pattern in two patients: Similar pattern B type findings have been reported by Mounsey[18] correlating phonocardiographic (pericardial knock) and hemodynamic measurements in the right side of the heart in patients with constrictive pericarditis. He described two patients who had no pericardial knock and a less abrupt and smoothly merging upstroke of the diastolic pressure dip in the right ventricular pressure recording. Pattern B could be explained by vascular volume depletion or by less severe constriction. Our two patients (Patient 2 and 6, Table II) had elevated right atrial, pulmonary wedge and ventricular diastolic filling pressures at the time of the cardiac catheterization, suggesting that they did not have significant volume depletion. One of these two patients (Patient 6, Table IV) had a thick fibrous pericardium, which was not adherent to the visceral pericardium (epicardium), suggesting that there was less severe constriction than in the pattern A patients, despite the typical hemodynamic findings. Another explanation for the lack of sudden limitation of left ventricular filling is that the right ventricle, which was not evaluated by angiography in this study, was less constricted than the left. The septum could then have provided continuing diastolic displacement at the expense of less impeded right ventricular filling. Alternatively, if the right ventricle was more constricted than the left, the left ventricle would have exhibited no sudden limitation of filling.

Mechanisms of the pericardial knock: The precise mechanism by which the sudden limitation of ventricular filling in constrictive pericarditis is converted to the sound of the pericardial knock is not clarified by our study, but two possibilities are suggested: (1) A "water-hammer" effect may be induced by abrupt deceleration of blood filling the ventricles, and the knock is produced by closely coupled secondary vibrations of chamber blood, ventricular walls, valves and pericardium, a mechanism similar to that proposed for the ventricular gallop sound. (2) A "sail-flop" phenomenon occurs, as in the cases of the opening snap of mitral stenosis or the ejection click of congenital aortic or pulmonary stenosis by which sudden tautening of a containing membrane (the pericardium in the current case) directly creates vibrations at audible frequencies which then are transferred to adjacent structures, such as the ventricular walls, chamber blood and chest wall tissues. Because both ventricles are usually involved by constriction, it is likely that they are involved in these phenomena, and that filling curves of the right ventricle would closely resemble those that have been demonstrated for the left ventricle in our study.

Maastricht, The Netherlands

In 7 of 43 patients in whom a sustained ventricular tachycardia could be induced during programmed electrical stimulation by a single ventricular premature stimulus, an identical tachycardia could also be initiated by a single atrial premature stimulus. This phenomenon was observed only in those patients in whom the ventricular tachycardia could be induced by a single ventricular extrastimulus having a prematurity index (ratio between the longest ventricular premature stimulus interval resulting in tachycardia and the duration of the basic cycle length of the paced ventricular rhythm) above 54 percent. No single instance of initiation of ventricular tachycardia by atrial premature stimuli was observed in patients with a ventricular prematurity index below 54 percent or requiring more than one consecutive ventricular extrastimulus to have tachycardia initiated. Other features of patients showing initiation of ventricular tachycardia by atrial premature stimuli were a right bundle branch block configuration of the QRS complex during tachycardia in all seven patients and a relatively slow rate during tachycardia. In one patient ventricular tachycardia was terminated by a conducted atrial premature stimulus.

Instances of ventricular tachycardia initiated by a supraventricular stimulus have been reported in human beings.[1–8] However, no study has been reported of the incidence of this phenomenon or of its electrophysiologic determinants in a large series of patients with ventricular tachycardia. In this article these aspects are analyzed and their possible therapeutic implications discussed in a series of 54 patients with clinically documented recurrent episodes of sustained ventricular tachycardia in whom an identical arrhythmia was induced during a stimulation study.

Methods

Patients: Data on 54 patients having recurrent sustained ventricular tachycardia in whom the arrhythmia could reproducibly be initiated and terminated by programmed electrical stimulation of the heart were reviewed. In all patients the tachycardia initiated during the stimulation study was similar to the one clinically documented. In none of the patients was the tachycardia initiated during exercise or after a spontaneous atrial extrasystole. In all patients administration of drugs was discontinued at least five half-lives before the study.

Protocol: Methods of stimulation and recording used in our laboratory have previously been described.[6] All patients had an A-H interval during sinus rhythm (measured on the His bundle electrogram from the first fast deflection of the atrial electrogram to the beginning of the fast deflection of the His potential) of more than 60 ms and showed normal prolongation of the A-H interval after administration of atrial test stimuli and during atrial pacing at increasing rates. Anterograde conduction over an accessory atrioventricular (A-V) pathway was

Address for reprints: Hein J. J. Wellens, MD, Department of Cardiology, Annadal Hospital, University of Limburg, Maastricht, The Netherlands.

excluded by observing no change or an increase in the H-V interval after A-V conduction of atrial premature stimuli during atrial pacing at a regular paced rhythm and atrial pacing at increasing rates. The diagnosis of a ventricular origin of the tachycardia was based on the presence of a widened QRS complex (0.12 second or more) not preceded by a His bundle deflection or an H-V interval that was less than the interval recorded during sinus rhythm. After informed consent was obtained, single test stimulation during a regular paced rhythm as well as pacing at increasing rates was performed from the atrium and ventricle in all patients. Atrial and ventricular extrastimulus testing was performed at basic cycle lengths of 600 and 500 ms in all patients; if possible, a cycle length between 600 ms and the sinus cycle length was also utilized. If no tachycardia could be initiated using this protocol of stimulation, up to three ventricular premature stimuli were given during a ventricular paced rhythm at the same basic cycle lengths as previously stated. In all patients timed atrial and ventricular premature stimuli were given during tachycardia with use of the synchronizing circuit of the stimulator. All data were statistically analyzed using Student's t test.

Definition of terms: The following terms are used throughout the study:

V_1-V_2 during atrial extrastimulus testing: interval between the ventricular complex resulting from the last complex of the basic atrial rhythm and the ventricular complex that follows the atrial test stimulus.

V_1-V_2 during ventricular extrastimulus testing: premature stimulus interval of the ventricular extrastimulus delivered during a regular ventricular paced rhythm.

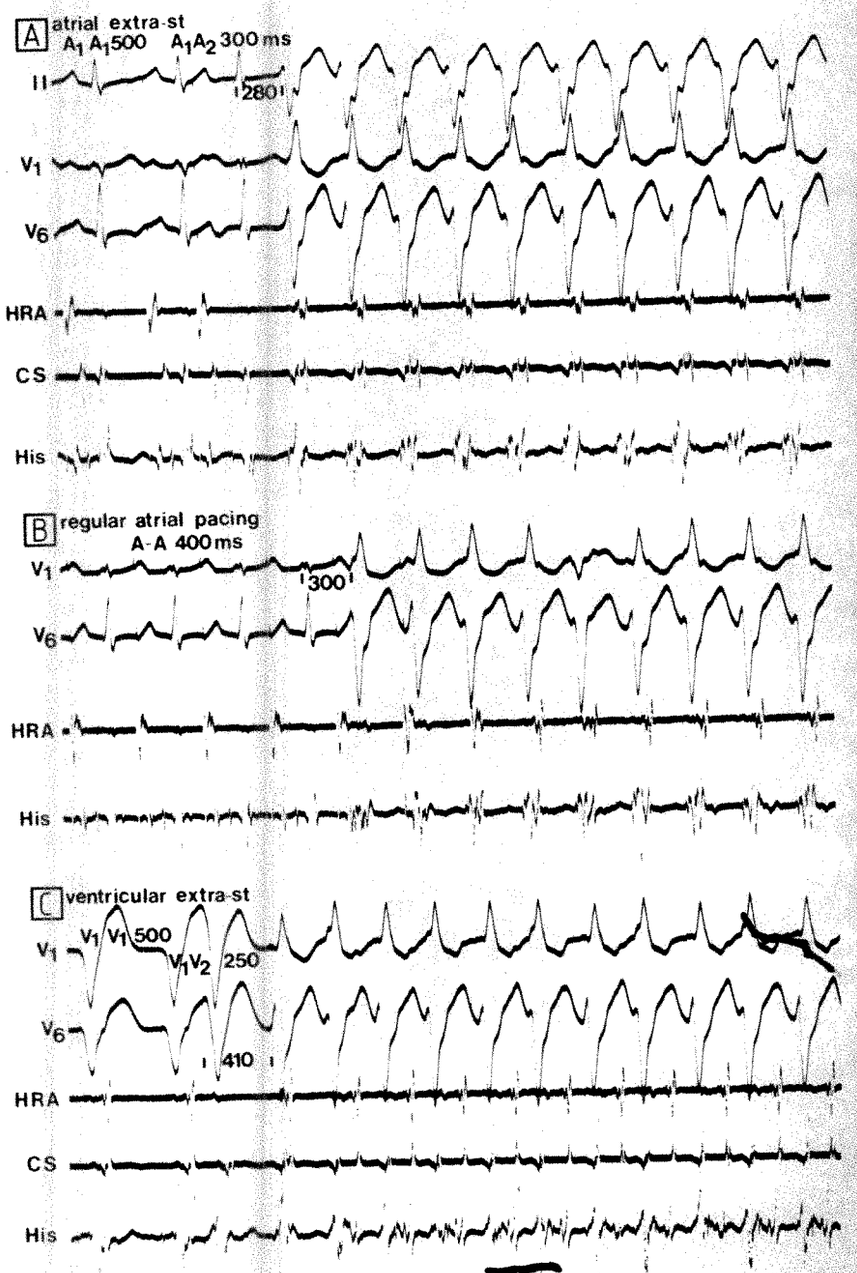

FIGURE 1. Initiation of ventricular tachycardia by **(A)** a critically timed right atrial premature stimulus (atrial extra-st) during atrial pacing, **(B)** rapid atrial pacing on reaching a pacing rate of 150 beats/min, and **(C)** a critically timed right ventricular premature beat (ventricular extra-st) during ventricular pacing. Simultaneous recordings of leads V_1, V_6, a high right atrial lead (HRA), a coronary sinus lead (CS) and a His bundle lead (His) are shown; in **A**, lead II is shown as well.

Prematurity index: ratio between the longest V_1-V_2 interval resulting in tachycardia during a ventricular paced rhythm and the basic cycle length (V_1-V_1) of the latter.

Results

Initiation of ventricular tachycardia: Ventricular tachycardia could reproducibly be initiated during programmed electrical stimulation of the heart in 54 patients. In all patients the induced tachycardia had the same configuration as that documented outside the cardiac laboratory. In 43 patients initiation of tachycardia could be accomplished by a single ventricular premature stimulus during ventricular pacing. In seven of these 43 patients a tachycardia with the same configuration and rate could also be initiated by a single atrial premature stimulus during atrial pacing. In all seven patients the QRS complex following the atrial premature stimulus was similar to the QRS complexes of the basic paced atrial rhythm. In two of the seven patients ventricular tachycardia could also be initiated by regular atrial pacing at increasing rates (Fig. 1). Because of the conduction characteristics of the A-V node, two patients had two zones of atrial premature stimulus intervals leading to ventricular tachycardia (Fig. 2 and 3). In none of the patients requiring two or more consecutive ventricular premature stimuli to initiate the ventricular tachycardia was the arrhythmia induced during atrial stimulation.

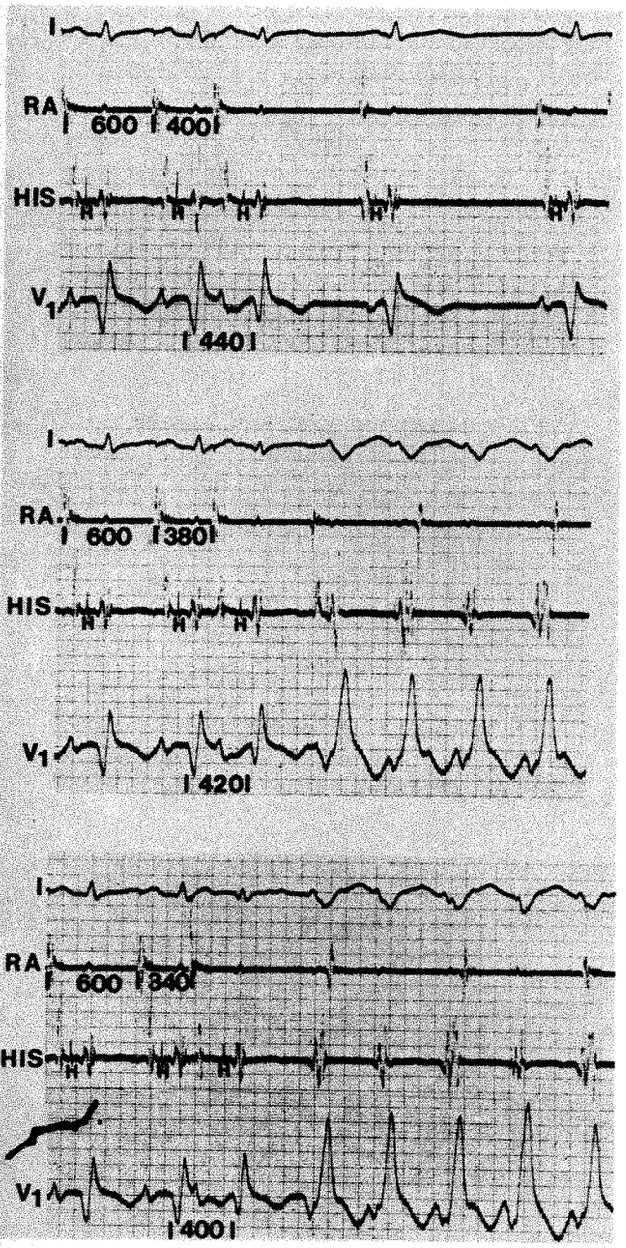

FIGURE 2. Upper panel, no initiation of ventricular tachycardia by an atrial premature stimulus of 400 ms during atrial pacing. **Middle panel,** ventricular tachycardia is initiated when an atrial premature stimulus given after an interval of 380 ms reaches the ventricle 420 ms after the ventricular complex resulting from the last stimulus of the basic atrial paced rhythm. **Lower panel,** further shortening of the atrial premature stimulus interval to 340 ms results in arrival of the impulse in the ventricle 400 ms after the last ventricular complex of the basic paced atrial rhythm and initiation of tachycardia.

Data from the seven patients in whom the tachycardia could be initiated by single atrial and ventricular premature stimuli (group A) were compared with those obtained in the 36 patients in whom ventricular tachycardia could be induced only by a single ventricular premature stimulus during ventricular pacing (group B). In three patients in group B, the longest V_1-V_2 interval leading to tachycardia during ventricular pacing was longer than the shortest V_1-V_2 interval attainable during atrial pacing at the same basic cycle length. In the remaining 33 patients of group B the shortest possible V_1-V_2 interval during atrial extrastimulus testing was longer than the longest V_1-V_2 interval required to initiate tachycardia during ventricular pacing.

In four patients in group A the longest V_1-V_2 interval leading to tachycardia during atrial extrastimulus testing was 20 to 40 ms shorter than the longest V_1-V_2 interval initiating tachycardia during a ventricular paced rhythm at the same basic cycle length. In the remaining three patients in group A the longest V_1-V_2 interval able to initiate tachycardia during atrial extrastimulus testing was similar (within a range of 10 ms) to the longest ventricular premature stimulus interval initiating tachycardia during ventricular pacing at the same basic cycle length.

Age, sex and cause of tachycardia: The age in group A ranged from 19 to 76 years (mean 45) and in group B from 19 to 81 years (mean 48). In group A 5 patients were male and 2 were female, whereas in group B 28 were male and 8 female. Four patients in group A and 25 in group B had an old myocardial infarction. Idiopathic ventricular tachycardia was present in 3 patients in group A and in 11 patients in group B. There were no statistical differences between groups A and B in age, sex or underlying heart disease.

QRS configuration during tachycardia, rate of tachycardia, tachycardia zone and prematurity index: All seven patients in group A had a right bundle branch block configuration during tachycardia and two had a complete right bundle branch block pattern

during sinus rhythm (Fig. 2 and 3). All patients in group A had a normal H-V interval during sinus rhythm. In 16 of the 36 patients in group B, the QRS complex during tachycardia had a left bundle branch block configuration (probability [p] <0.05).

Heart rates during ventricular tachycardia ranged from 120 to 180 beats/min (mean ± standard error of the mean 143 ± 20) in group A and from 110 to 220 beats/min (mean 172 ± 29) in group B. The widest zone of premature stimulus intervals resulting in tachycardia during ventricular extrastimulus testing with any of the basic cycle lengths that were used ranged from 80 to 300 ms (mean 134 ± 41) in group A and from 20 to 170 ms (mean 47 ± 21) in group B.

- *In assessing the ability to initiate ventricular tachycardia by ventricular premature stimuli,* we also determined the ratio between the longest V_1-V_2 interval leading to tachycardia during ventricular extrastimulus testing and the basic cycle length of the ventricular paced rhythm (V_1-V_1). This ratio was called the ventricular prematurity index and in patients in group A it ranged from 55 to 85 (mean 71 ± 11) percent and in group B from 32 to 52 (mean 41 ± 8) percent. These differences between groups A and B in QRS configuration and rate during tachycardia, the zone of premature stimulus intervals resulting in tachycardia and ventricular prematurity index of the longest V_1-V_2 interval leading to tachycardia during ventricular extrastimulus testing were statistically significant (p <0.01).

Termination of ventricular tachycardia by an atrial premature stimulus: In 10 patients atrial premature stimuli given during tachycardia were conducted to the ventricles. This resulted in fusion complexes in four patients and complete "captures" in six. In only one patient (in group B) could the tachycardia be terminated by a conducted supraventricular impulse. As shown in Figure 4, the tachycardia that had a rate of only 110 beats/min could be terminated by both a single ventricular premature stimulus and a conducted single atrial extrastimulus. The maximal rate of this tachycardia observed during the stimulation study was 120 beats/min (Fig. 5).

Discussion

Isolated examples of ventricular tachycardia induced after supraventricular impulses have previously been reported.[1–4,7,8] In the largest series of ventricular tachycardia induced by programmed electrical stimulation of the heart so far reported,[5,6,9] the characteristics and implications of the initiation of this arrhythmia by supraventricular stimuli were not analyzed.[5,6,9]

Incidence: Initiation of ventricular tachycardia by supraventricular impulses is not rare. In this series of 43 patients in whom a ventricular tachycardia could reproducibly be initiated during programmed electrical stimulation of the heart by a single timed ventricular premature impulse, an identical tachycardia could also be induced by atrial premature stimuli in 7 patients. This represents an incidence rate of 16 percent. In contrast, termination of a ventricular tachycardia by supraventricular extrastimuli is a very rare observation and was found in only one patient in our series.

Electrophysiologic Determinants

Initiation of ventricular tachycardia by supraventricular stimuli: This phenomenon seemed to be determined in our patients by the ease of initiation of

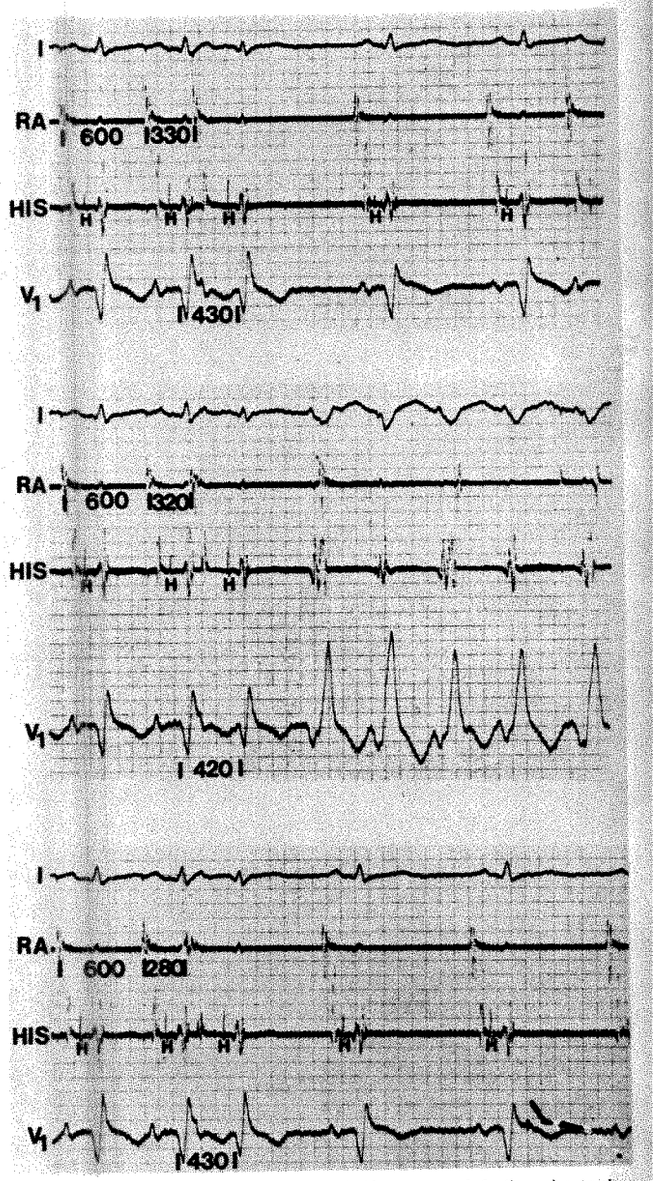

FIGURE 3. Same patient as in Figure 2. **Upper panel,** further shortening of the atrial premature stimulus interval to 330 ms results in prolongation of atrioventricular (A-V) nodal conduction time leading to delayed arrival of the impulse in the ventricle. Now the interval between this ventricular complex and the preceding ventricular complex measures 430 ms, which exceeds the upper limit of the tachycardia zone (420 ms, **middle panel** Fig. 2) and no tachycardia is initiated. **Middle panel,** when the atrial premature stimulus is given 10 ms earlier, the interval at the ventricular level lengthens again to 420 ms with initiation of tachycardia. **Lower panel,** further shortening of the atrial premature stimulus interval results in arrival at the ventricular level outside the upper limit of the tachycardia zone.

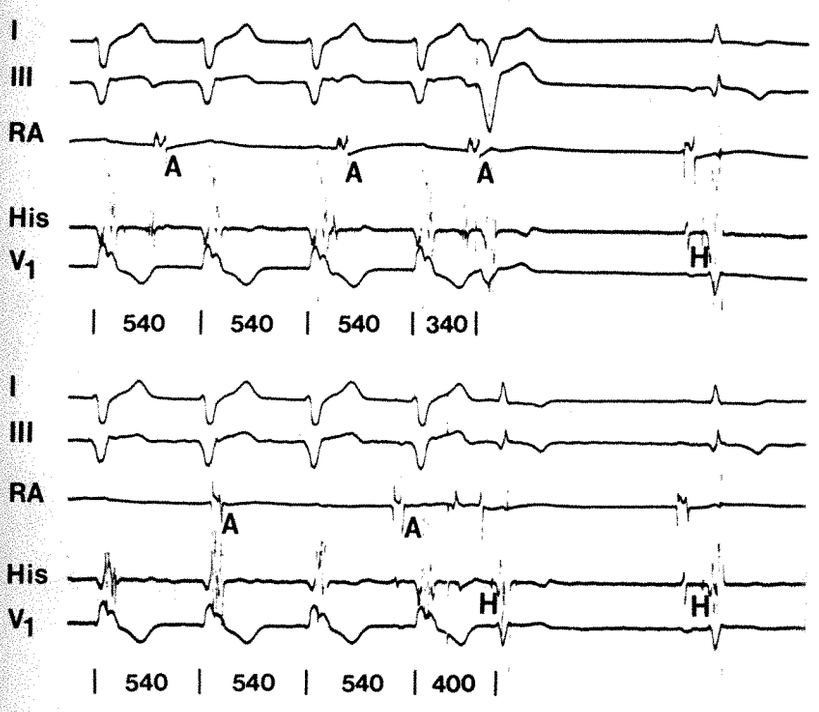

FIGURE 4. Termination of a ventricular tachycardia with a slow rate (110 beats/min) by an electrically induced ventricular (**upper panel**) and atrial (**lower panel**) premature stimulus. **Upper panel,** 3: 2 ventriculoatrial (V-A) Wenckebach conduction is present. **Lower panel,** termination of tachycardia by the conducted atrial premature impulse is possible because of the low rate during tachycardia, permitting arrival of the atrial impulse in the ventricle (in spite of delay in the atrioventricular (A-V) node) early enough to enter the ventricular reentry circuit to terminate tachycardia. The slow rate of the tachycardia might suggest this arrhythmia to be an example of an accelerated idioventricular rhythm. However, the arrhythmia could reproducibly be initiated by premature ventricular stimuli during ventricular pacing. We have never observed this phenomenon during stimulation studies in patients with documented accelerated idioventricular rhythm.

the tachycardia. First, initiation of ventricular tachycardia by atrial premature stimuli was observed only in patients in whom no more than a single ventricular premature stimulus was required to induce the arrhythmia. Second, in the latter group of 43 patients, atrial premature stimuli were able to initiate ventricular tachycardia only in those patients in whom the prematurity index of the longest V_1-V_2 interval resulting in tachycardia during ventricular extrastimulus testing was above 54 percent.

No overlap in prematurity index existed between group A (patients in whom ventricular tachycardia was inducible by both one ventricular and one atrial premature stimulus) and group B (tachycardia induced by only one ventricular extrastimulus during ventricular pacing). Thus, when a ventricular tachycardia can be induced by a ventricular extrastimulus with a prematurity index above 54 percent, it seems likely that the same tachycardia will be initiated by atrial premature impulses.

The time of arrival of the initiating impulse to the ventricles is not the only factor determining the induction of a ventricular tachycardia by a supraventricular stimulus. This is illustrated in three of our patients in whom tachycardia could be initiated only by a ventricular premature stimulus even though the tachycardia zone during ventricular extrastimulus testing occurred at longer V_1-V_2 intervals than the shortest V_1-V_2 interval attainable during atrial extrastimulus testing at the same basic cycle length. In addition, four patients in group A the longest V_1-V_2 interval resulting in the initiation of ventricular tachycardia during atrial extrastimulus testing was shorter than the longest V_1-V_2 interval required to induce tachycardia during ventricular stimulation at the same basic driving rate. These observations suggest that the site of stimulation and the direction and spread of the excitatory wave also play important roles in the initiation of ventricular tachycardia.[6,10]

Although it is understandable that patients with ventricular tachycardia whose arrhythmia can be initiated by a supraventricular stimulus have a wide tachycardia zone and a longer prematurity index during testing by the ventricular extrastimulus technique, the lower mean ventricular rate during tachycardia in patients in group A than in those in group B is more difficult to explain. As demonstrated by Josephson et al,[11] the reentry circuit underlying most instances of chronic recurrent sustained ventricular tachycardia is very likely of small size, suggesting that slow conduction is the main electrophysiologic determinant of the heart rate during ventricular tachycardia. If in a region of impaired conduction a certain value of refractoriness exists, the slower the conduction velocity within a reentry circuit, the easier it will be to reexcite the initially blocked region and to initiate tachycardia. This is probably why a statistically significant relation was found between the ease of initiation of tachycardia (as defined by the prematurity index) and the ventricular rate during the arrhythmia in those patients in whom a single conducted atrial premature stimulus was the only requirement to create unidirectional block (refractoriness) within the circuit.

Termination of ventricular tachycardia by supraventricular stimuli: The rarity of this phenomenon (observed in only 1 of 43 patients) is not surprising. If reentry is the mechanism of the arrhythmia, termination of the tachycardia by a premature stimulus re-

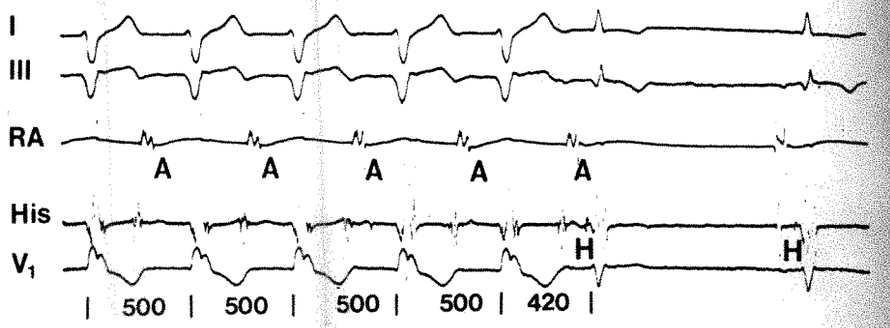

FIGURE 5. Same patient as in Figure 4. During ventricular tachycardia 1:1 ventriculoatrial (V-A) conduction is present. The increase in V-A conduction time after the fifth QRS complex of the tachycardia is followed by an atrioventricular (A-V) nodal echo impulse. This echo impulse terminates tachycardia spontaneously.

quires invasion into the reentry circuit and creation of refractoriness ahead of the circulating impulse by the premature stimulus. Only when the rate of the ventricular tachycardia is relatively slow can a premature supraventricular impulse pass the delaying area of the A-V node and capture the ventricles with sufficient prematurity as to enter the reentry circuit at the appropriate time to terminate the arrhythmia. Rates of 110 to 120 beats/min are not frequent during ventricular tachycardia,[5,9] although in a previous report from our group[12] rates below 130 beats/min were found in 9 of 70 different ventricular tachycardias observed in 62 patients.

In the patients in this study the rather slow ventricular tachycardia was observed to terminate not only after a conducted atrial premature stimulus but also spontaneously by an A-V nodal echo impulse (Fig. 4 and 5). This type of termination of ventricular tachycardia by a supraventricular impulse should be differentiated from the also rare observation of termination by a nonconducted supraventricular impulse of a tachycardia based on a reentrant mechanism using the bundle branch system.[13]

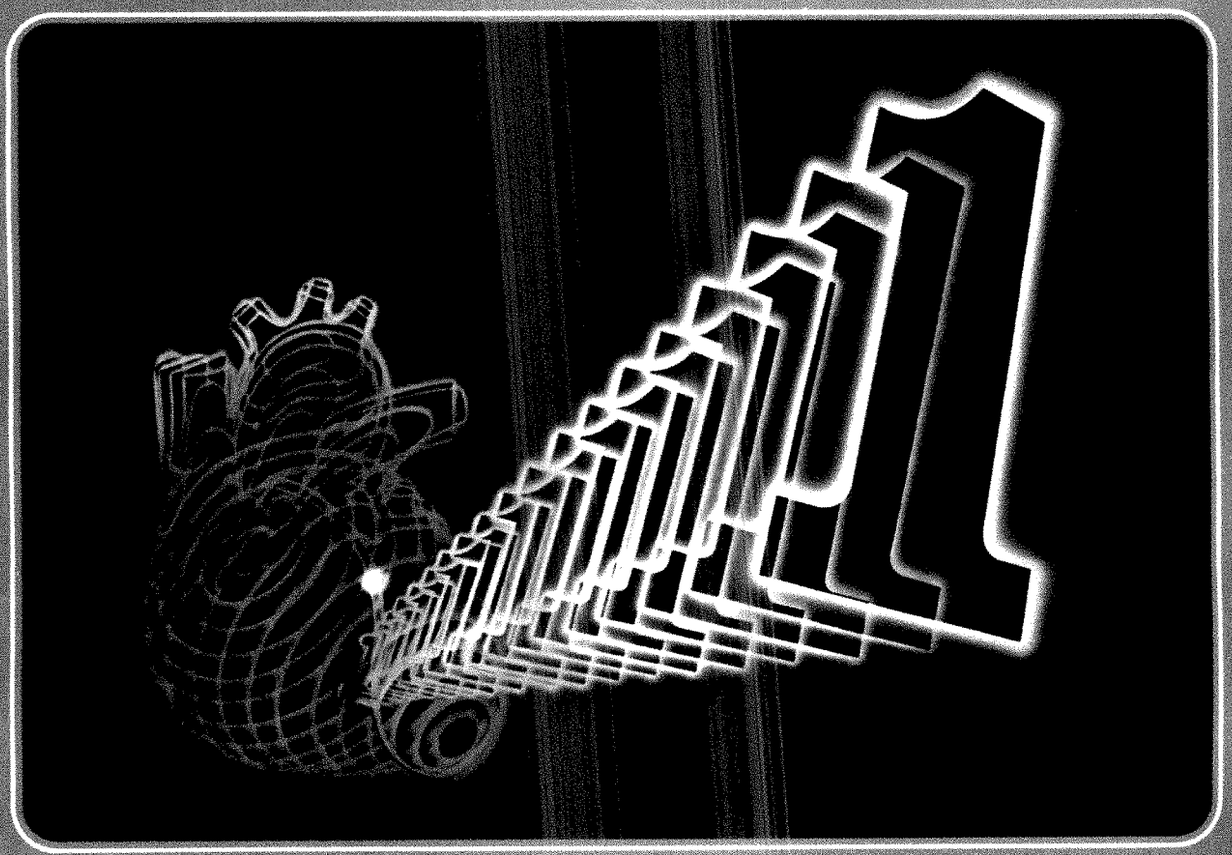
QRS configuration in ventricular tachycardia induced by atrial impulses: The association between the ability to induce a ventricular tachycardia by supraventricular impulses and a right bundle branch block configuration during tachycardia has been found in other reported examples.[1,4,6,8] We cannot offer an explanation for our finding that all the ventricular tachycardias that were induced by both single atrial and ventricular premature impulses had a right bundle branch block configuration.

Comparison with previously reported electrophysiologic findings: The observations mentioned previously are in accord with the electrophysiologic characteristics of the patient reported on by Denes et al.[5] in whom a ventricular tachycardia could be induced by an atrial extrastimulus. Ventricular tachycardia in their patient had a right bundle branch block configuration and a rate between 130 and 180 beats/min. In addition, this tachycardia could be induced by a single ventricular extrastimulus within a wide zone of premature impulse intervals (180 ms), the ventricular prematurity index being 67 percent. In another patient in their series, ventricular tachycardia could be induced after cessation of atrial pacing as well as by a single ventricular premature stimulus. Data to assess whether this patient did or did not have the other characteristics found in our patients are not given in the study.

Josephson et al.[9] described a patient in whom ventricular tachycardia was induced by rapid atrial pacing and by single ventricular extrastimuli. No additional information was given to allow comparison with our patients. Finally, Zipes et al.[8] described three patients in whom a ventricular tachycardia was initiated by supraventricular impulses. In the only patient in whom the ventricular tachycardia could be initiated by single atrial premature stimuli, the arrhythmia was not induced by ventricular premature stimuli. The number of basic cycle lengths used during ventricular extrastimulus testing and data on whether this technique was applied at one or more ventricular endocardial sites are not given. As discussed elsewhere,[6] both features (basic cycle length and site of stimulation) are important determinants of the ease of initiation of ventricular tachycardia. These factors might account for the apparent discrepancies between the patient of Zipes et al. and our patients.

Clinical Implications

The observation that ventricular tachycardia can be initiated by an atrial premature stimulus is of clinical importance. In fact, clinical examples of initiation of both ventricular tachycardia and ventricular fibrillation after supraventricular conducted impulses have been reported.[1,7,14] One of the main practical implications of our study may be related to the possible modifications in the ease of initiation of ventricular tachycardia after administration of antiarrhythmic drugs. These might occur when the drug does not significantly affect the A-V nodal properties but induces in the ventricular reentry circuit a reduction in conduction velocity that is greater than the prolongation of refractoriness. We[15] previously reported on the effect of procainamide in 12 patients with recurrent sustained ventricular tachycardia. After the administration of procainamide in all eight patients in whom the arrhythmia was still inducible, ventricular premature stimuli given at longer premature stimulus intervals were able to initiate ventricular tachycardia. In three of these eight patients the prematurity index increased from a value below 48 percent to one above 56 percent after administration of antiarrhythmic drugs. The observation of initiation of



ventricular tachycardia by later ventricular premature stimuli after the administration of procainamide was also made by Horowitz et al.[16] This finding suggets that, under these circumstances, an atrial premature stimulus might have been able to induce ventricular tachycardia. Unfortunately, we did not test in our patients the effect of atrial premature stimuli on the initiation of tachycardia after the administration of procainamide. However, our findings suggest that in some patients ventricular tachycardia may not be prevented by giving a drug that can abolish ventricular premature complexes unless it also simultaneously eliminates atrial extrasystoles or significantly prolongs conduction time and refractoriness in the A-V node, or both.

Our study indicates that formation of an abnormal impulse at the supraventricular level may play a more important role in the initiation of ventricular tachycardia than previously realized. Although all our patients had normal A-V nodal function, such a mechanism would theoretically be further facilitated by abbreviation of the refractory period and acceleration of the conduction velocity of the A-V node by sympathomimetic or parasympatholytic influences. In all our patients the conducted supraventricular stimulus had a ventricular activation pattern that was similar to the one seen after the basic paced atrial rhythm. In view of the role of spread of ventricular excitation in the initiation of a ventricular reentrant mechanism,[6,10] it can be suspected that in some patients initiation of ventricular tachycardia by a conducted supraventricular impulse will only occur if the premature impulse is aberrantly conducted through the ventricle.

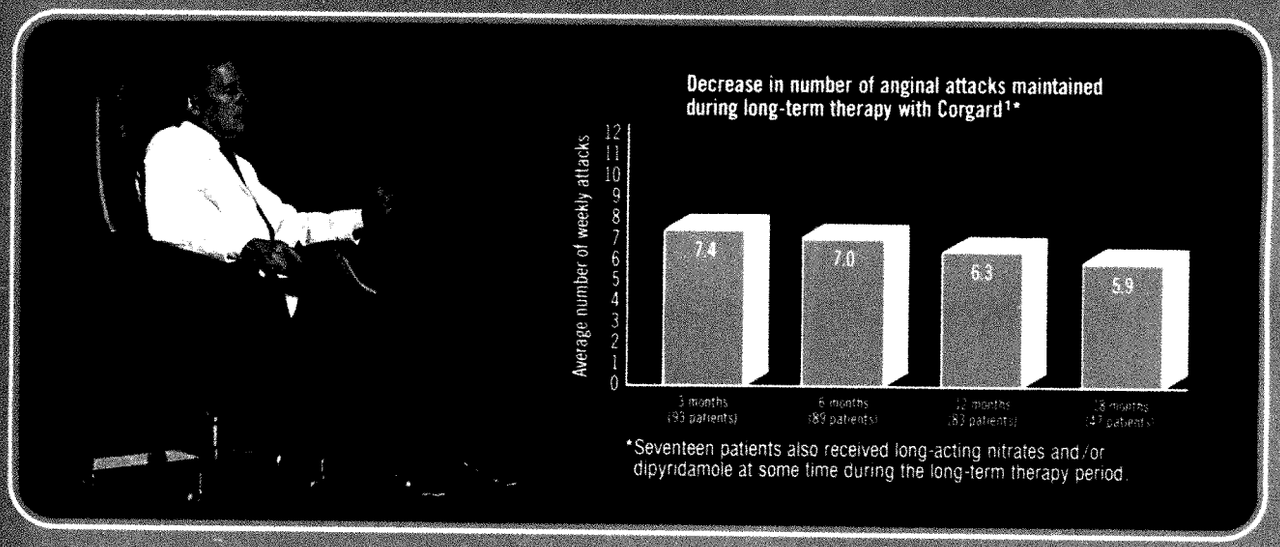
CORGARD®
nadolol tablets

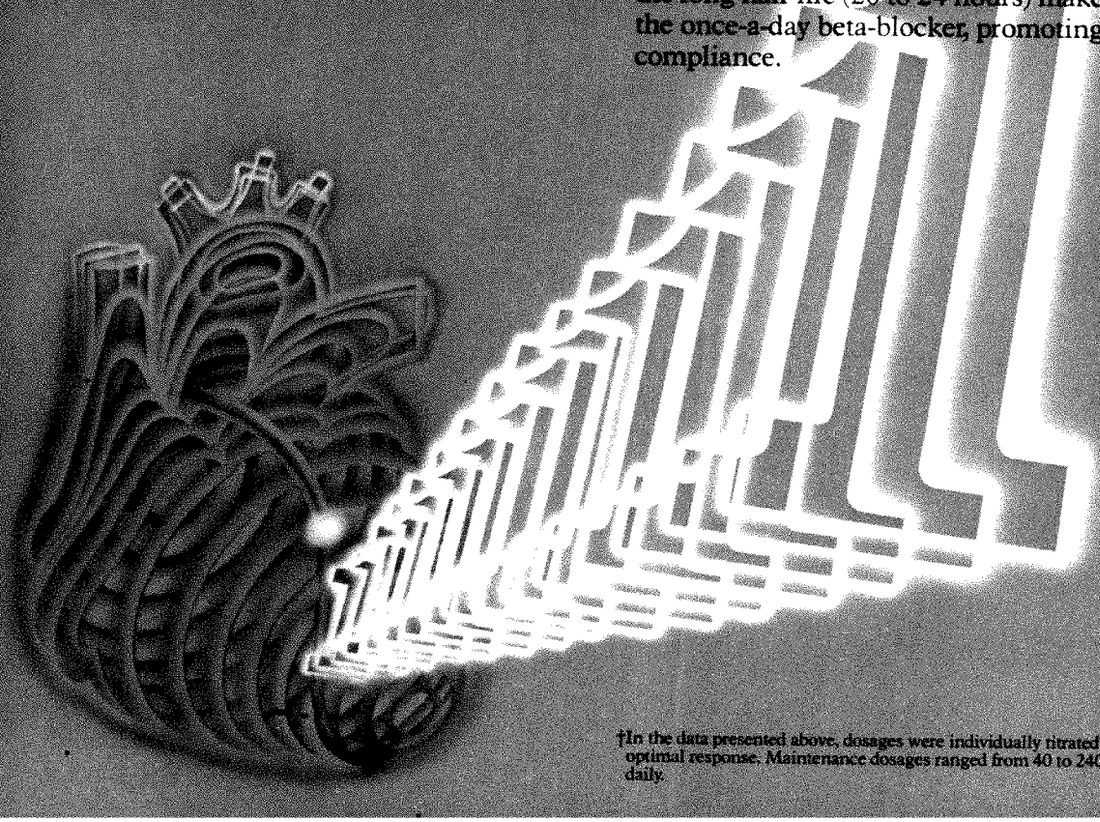


The first and only beta-blocker with once-a-day dosage

In the treatment of angina pectoris

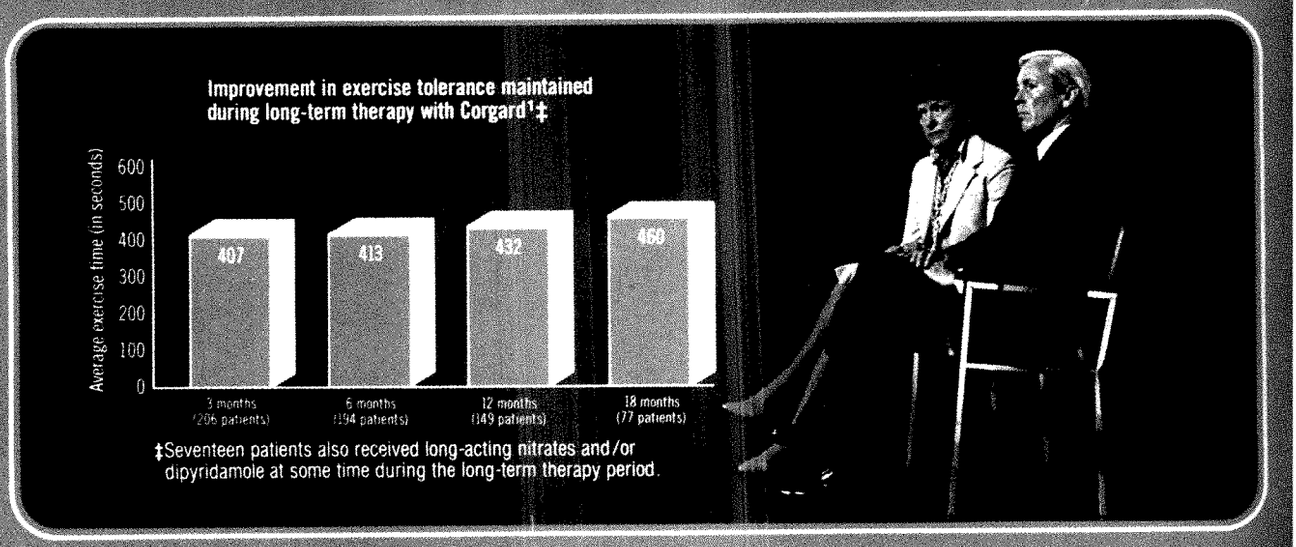
SQUIBB

See last page of this advertisement for brief summary.



CORGARD® (nadolol tablets):

Once-a-day, everyday, Corgard offers round-the-clock protection



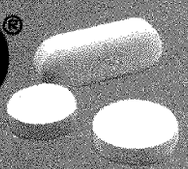
A single daily dose of Corgard offers prophylaxis in angina pectoris, helping to protect the patient all day and all night from painful attacks. And in extended clinical studies, the efficacy of Corgard — as demonstrated by a decreased rate of anginal attacks and an increase in exercise tolerance — was maintained.[1]

Once-a-day, everyday, Corgard decreases the frequency of anginal attacks

Corgard taken just once daily offers round-the-clock protection from angina pain. In one short-term study, Corgard, once a day, decreased the average number of anginal attacks per week in 115 patients with angina, from 13.6 pretherapy to 6.4 at the end of 14 weeks of therapy, a mean decrease of 59%.[1†] In 19% of the 115 patients, anginal attacks were completely eliminated. And the long half-life (20 to 24 hours) makes Corgard the once-a-day beta-blocker, promoting patient compliance.

†In the data presented above, dosages were individually titrated to achieve optimal response. Maintenance dosages ranged from 40 to 240 mg Corgard daily.

Effective control of angina pectoris



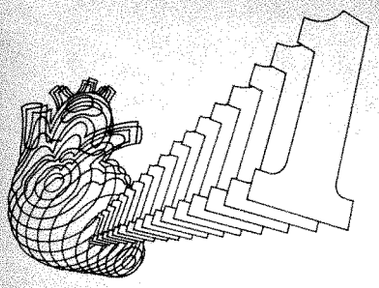
Once-a-day, everyday, Corgard increases exercise tolerance

Corgard allows the angina patient to do more. In 147 patients in the same short-term study as the one at left, Corgard, once a day, increased ergometry time by 25%, improving exercise tolerance from an average of 365 seconds pretherapy to 427 seconds at the end of 14 weeks of therapy.[1] In 21% of the 147 patients, the end point of exercise was fatigue rather than angina pain. And the single daily dose of Corgard can be taken at the patient's convenience, without regard to meals.

Once-a-day, everyday, Corgard decreases nitroglycerin usage[1]

Corgard blocks catecholamine influence on myocardial activity, decreases myocardial oxygen demand, and does not have a direct myocardial depressant effect.

Prescribe CORGARD® nadolol tablets



40 mg, 80 mg, and 120 mg tablets

The common-sense beta-blocker for angina pectoris

Effective control of angina pectoris... and hypertension

CORGARD®
nadolol tablets
40 mg, 80 mg, and 120 mg tablets

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of beta$_2$ receptors.

Major Surgery — Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. • **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a beta$_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 16(mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval — see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, or 120 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® single-dose packs of 100 tablets.

Now in book form...the latest **Update Your Medicine** lectures.

CORNELL MEDICAL UPDATE/2

Edited by LILA A. WALLIS, MD, FACP

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

All new material—specialties expanded.

The workbook format of the CORNELL MEDICAL UPDATE/2 breaks medical publishing traditions by giving practicing physicians a quick overview of the latest advances in their specialty. It transcribes the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical Center. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 5th Ave., N.Y., N.Y. 10103 AJC 10/80

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00. I may use the book for 30 days and if not completely satisfied, return it for full refund or credit.

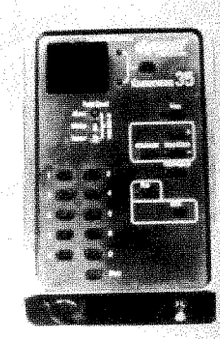
A dynamometer which measures physical work rates



Now with the new series of Dynavit equipment, graded exercise is possible on an ergometer with its own built-in calibrating dynamometer. Controlled pulses of current are fed through electrical windings of the braking system and a magnetic field is induced which becomes the braking torque to oppose the flywheel's rotation. The braking system is float mounted such that it responds in a counter torsion movement, and this is mechanically transmitted into a precision strain gauge.

And a phototachometer accurately counts the flywheel revolutions per minute. Therefore, the true and effective cranking effort (work rate = watts of power expended) is dynamometrically controlled. **Constant, calibrated and controlled work rates independent of pedal speed!**

world's first digital camera designed for the cardiologist.

Apex 215M: lightweight mobile cardiological gamma image

Apex 215M is a fully integrated nuclear system designed specifically for the cardiologist.
Apex 215M fulfills all the requirements of modern nuclear cardiology. Compact, exceptionally maneuverable, easy to position and extremely versatile, it combines superb single-crystal image quality with the ultra-high count rates previously obtainable only with low-resolution multicrystal cameras.

History: Acute Anterolateral wall MI. Catheterization showed 3 vessel CAD (LVEF=35%). Image shows defect of the Regional Ejection Fraction.
Diagnosis: lateral aneurysm.

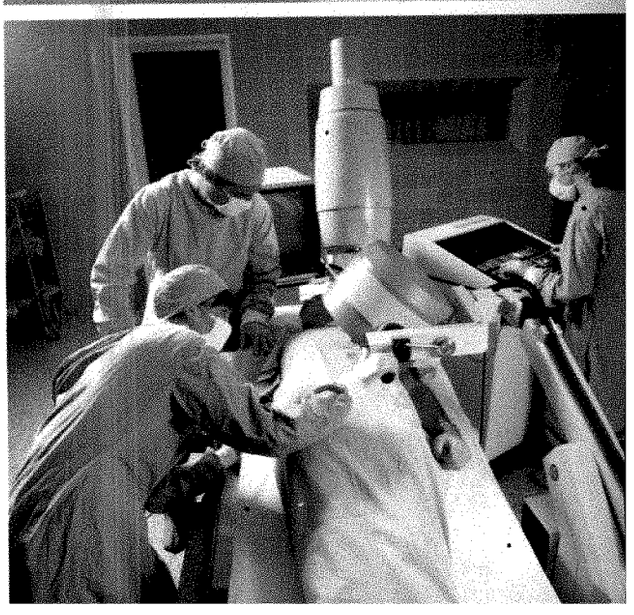
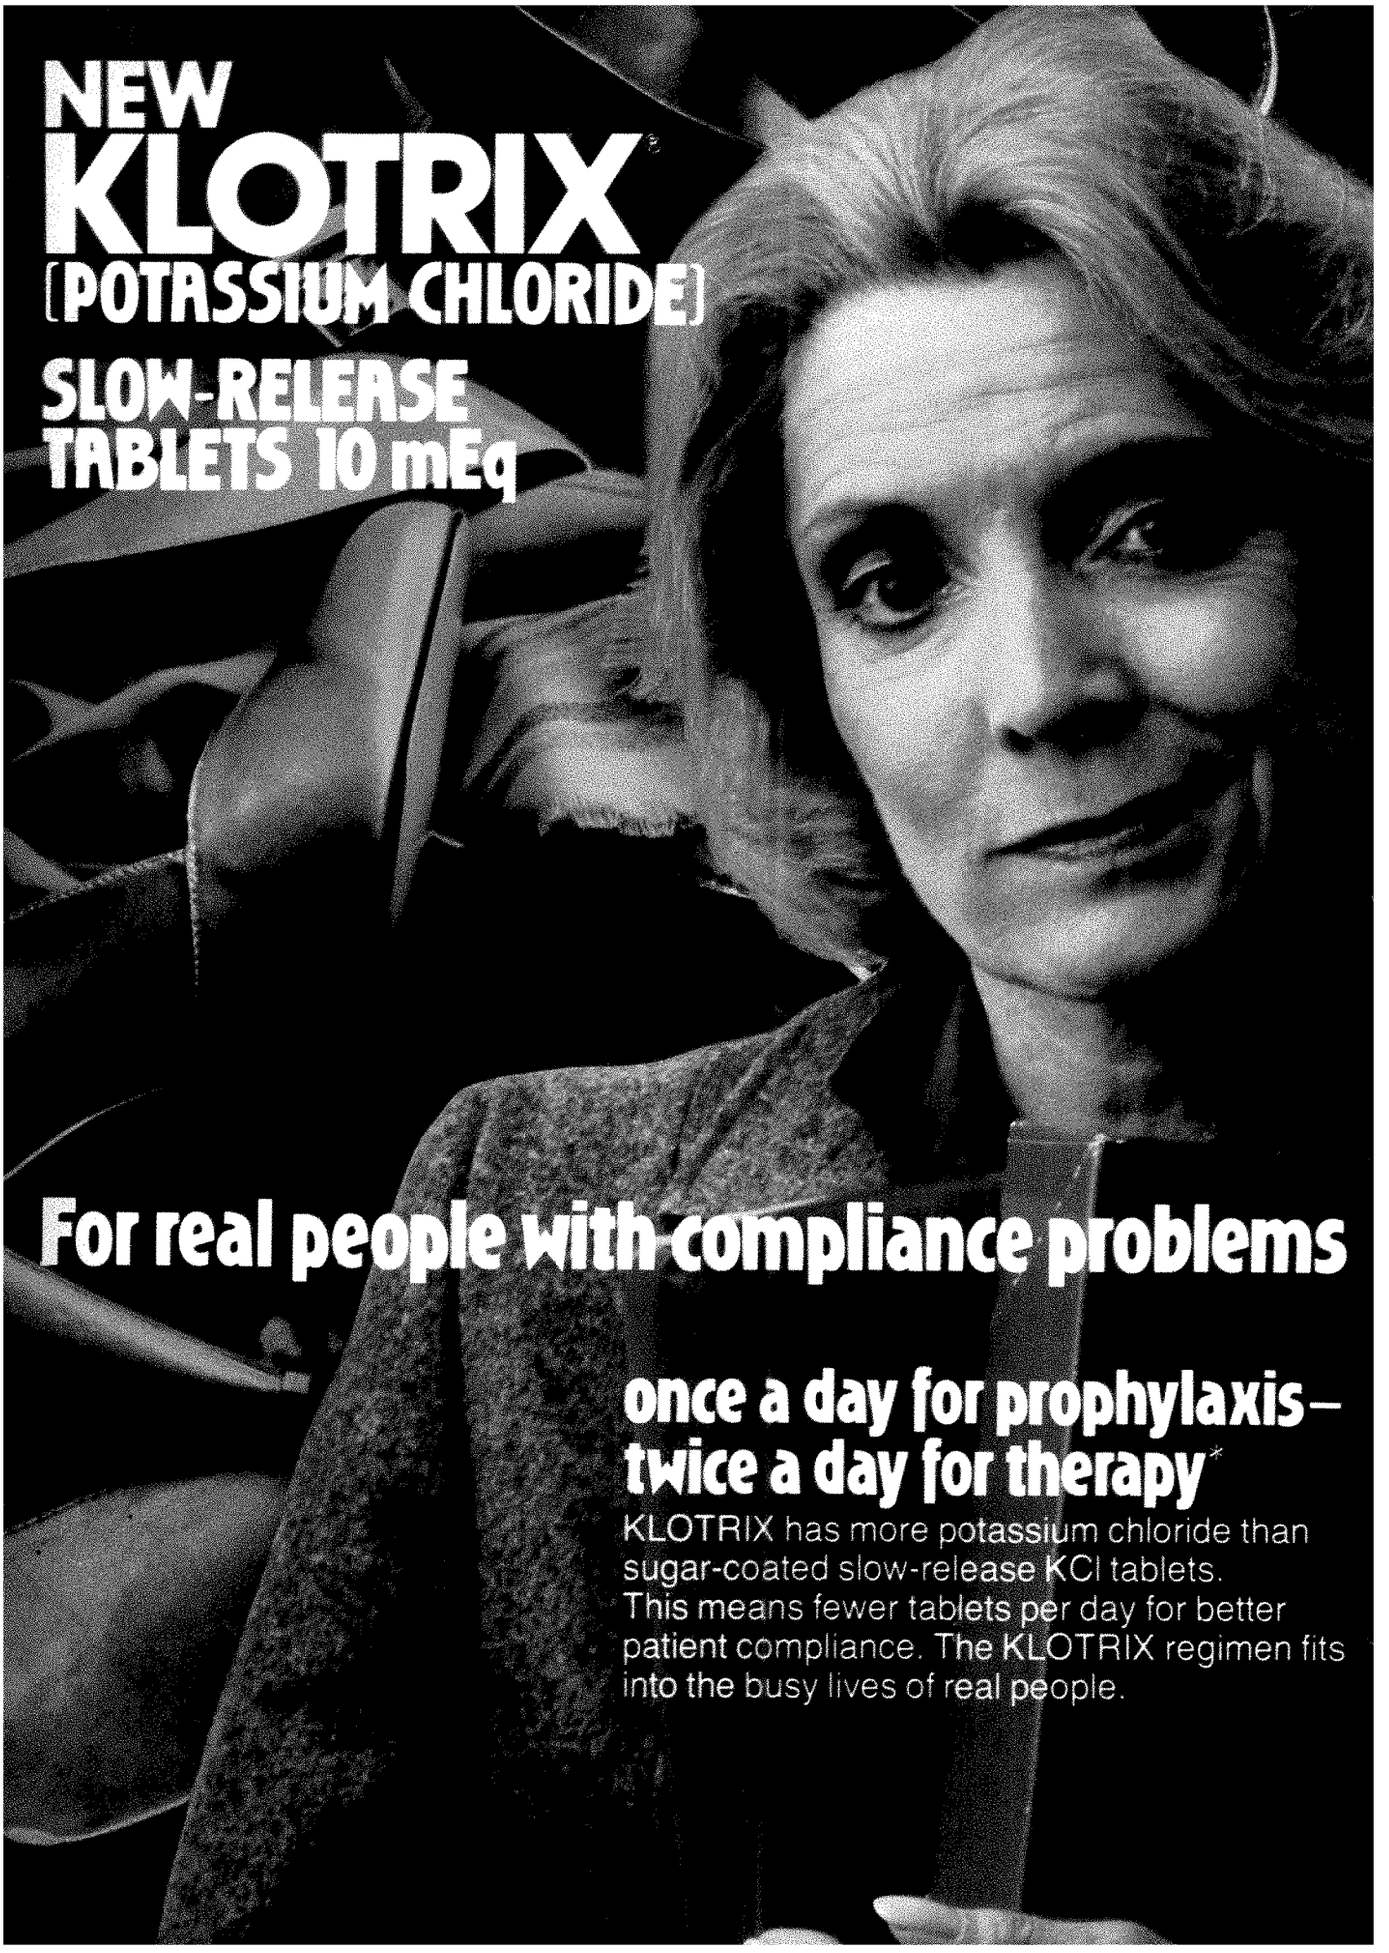
Universal Cardiological Capability

Crystal Clear First-Pass Examinations at count rates as high as 500,000 CPS and resolutions as fine as 1.8 mm (bar phantom). Unobstructed RAO dynamic views of distinct clarity.
Ultra-Fast Equilibrium Gated Dynamics at unprecedented combinations of frame rate and resolution (64 frames per heart cycle for 64^2 matrices), at rest or during exercise.
Superior Quality Static Myocardial Imaging with either ^{99}Tc pyrophosphate or ^{201}Tl. Images acquired and displayed on 512^2 matrices with 256 gray levels.





A Set of Dedicated Cardiological Programs, Continuously Enriched

Touch a functional pushbutton, and Apex 215M provides:

- Up to three simultaneous cine-views.
- Wall motion visualization and quantification.
- Ejection Fraction and Ejection Rate calculation.
- Remaining Fraction calculation.
- Static or dynamic Regional Ejection Fraction Imaging.
- End Diastole/Systole Volumes.
- Shunt quantification.

Programs unique to the Apex Line include special algorithms for diagnosing ventricular-atrial regurgitation and ventricular aneurysms. A whole new series of Apex clinical programs is now being tested.

NEW
KLOTRIX®
(POTASSIUM CHLORIDE)
SLOW-RELEASE
TABLETS 10 mEq
For real people with compliance problems
once a day for prophylaxis–
twice a day for therapy*
KLOTRIX has more potassium chloride than sugar-coated slow-release KCl tablets. This means fewer tablets per day for better patient compliance. The KLOTRIX regimen fits into the busy lives of real people.

...in the real world of soaring prices
25% lower in cost
KLOTRIX® (potassium chloride), the economical slow-release KCl supplement, can save your patients as much as 25%. KLOTRIX is priced to please in this world of soaring prices.
Mead Johnson
PHARMACEUTICAL DIVISION

© 1980 Mead Johnson & Company • Evansville, Indiana 47721 MJL O 4551

NEW KLOTRIX®
(POTASSIUM CHLORIDE)
SLOW-RELEASE TABLETS 10 mEq

DESCRIPTION KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS—BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with potassium-sparing diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram and clinical status of patient.

ADVERSE REACTIONS Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose. One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE Usual dietary intake potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: KLOTRIX slow-release tablets must be swallowed whole and never crushed or chewed.

HOW SUPPLIED Bottles of 100.

Mead Johnson PHARMACEUTICAL DIVISION

NITROSTAT®
(nitroglycerin tablets, USP)

INDICATIONS
Nitrostat is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

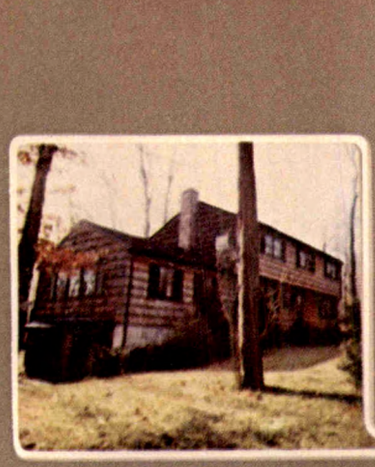
PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

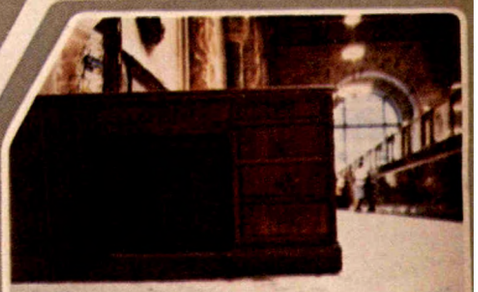
0.15 mg (1/400 grain): N 0071-0568-24 [06]—bottle of 100 tablets;
N 0071-0568-13—Convenience Package.



0.3 mg (1/200 grain): N 0071-0569-24 [06]—bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain): N 0071-0570-24 [06]—bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain): N 0071-0571-24 [06]—bottle of 100 tablets;
N 0071-0571-13—Convenience Package. **YF**



PARKE-DAVIS

PD-JA-0143-2-P(4-80)

security system...

- provides medication for emergency use at four different locations and thus assures a sense of security wherever the patient may be
- supplies a nitroglycerin more stable than conventional nitroglycerin tablets (Nitrostat has a five-year expiration date*)
- allows your patient to carry less medication than that packaged by most nitroglycerin manufacturers
- all four bottles needn't be opened at once, so that unused tablets in sealed bottles retain their potency

Your angina patients will feel better protected.

THE ECG OF THE 80's...

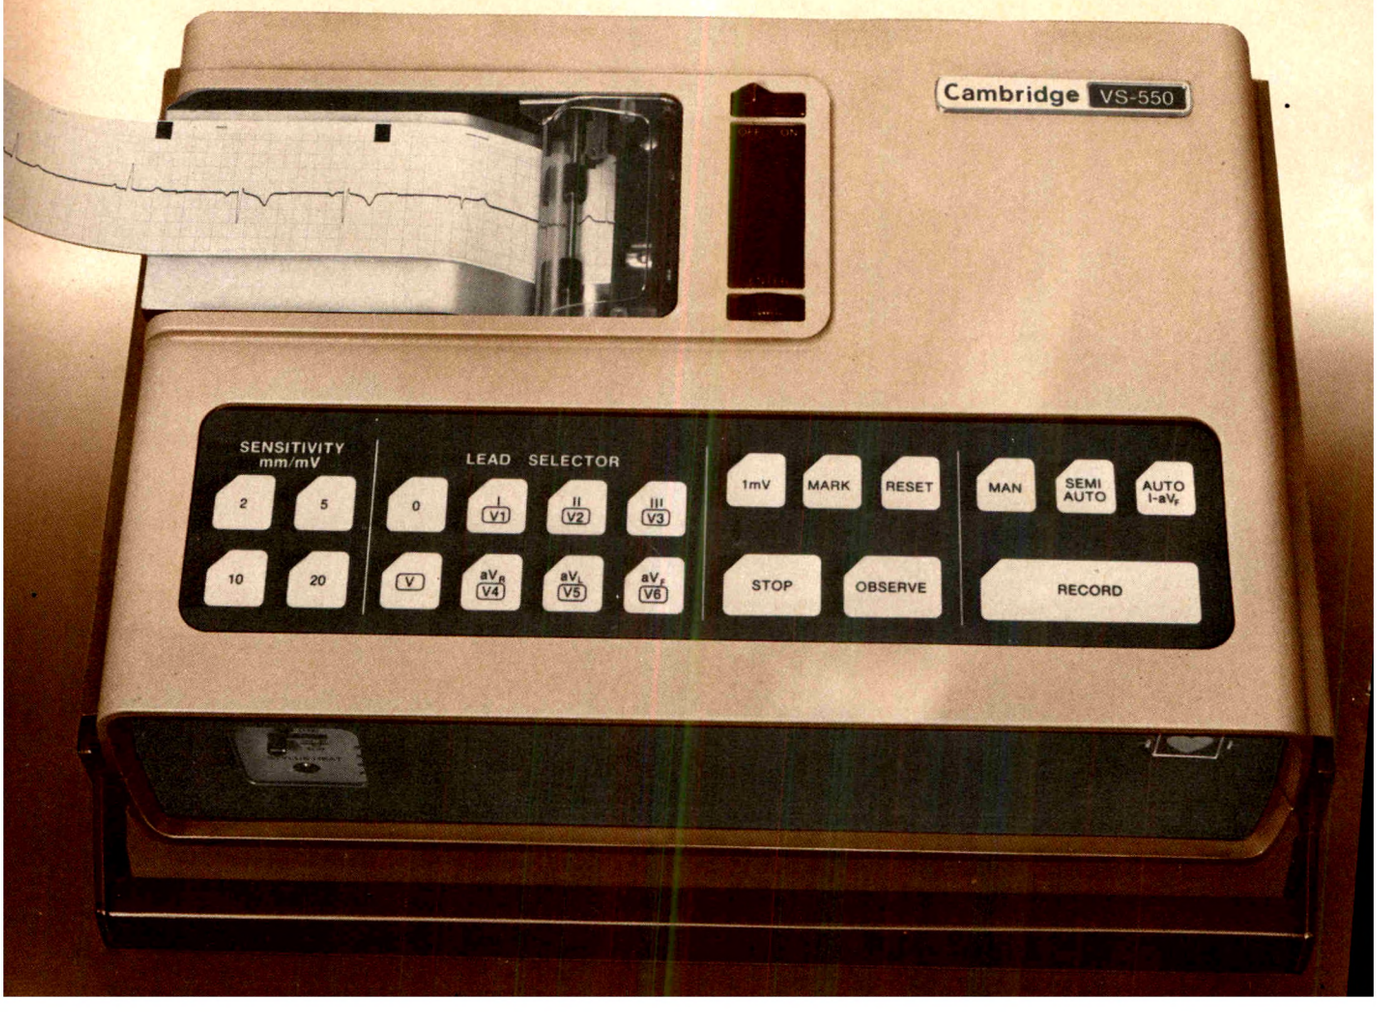
It Sets The Standard For Years To Come

The Standard For Cost Efficiency Total time from patient set-up through record mounting can be reduced by half, enabling labor cost savings in the competitively priced VS-550. The savings are due to the total system concept of the instrument...from automatic lead switching to the unique PERFform™ perforated paper and mounting system.

The Standard For Reliability New technology and over 60 years of experience...the VS-550 combines the best of both to give you high performance and reliability. The unit features a rugged high impact molded case, microprocessor-controlled circuitry, and a touch control panel that far surpasses in reliability, the standard mechanical lead selector switch.

The Standard For Operating Ease Simplicity of operation is achieved in the VS-550, from its instant paper loading through its automatic lead and calibration marking. And, at just the touch of a switch...an optional AC Eliminator removes line power interference without distorting the ECG.

The Standard For Serviceability The VS-550 has been designed for simplicity of service and has the ability to instantly analyze instrument performance, on demand, through the AUTOTEST™ program. Most service adjustments can be made without disassembly. Downtime is reduced to a minimum, because of plug-in modular construction and the backup you get from our nationwide service organization.



For demonstration or ordering information, please write or call collect: 73 Spring St., Ossining, N.Y. 10562, Tel: (914) 941-8100, Ext. 550.

LOPRESSOR®

*metoprolol tartrate

exerts a relative preference for beta-one receptors.

WORKS WHERE IT SHOULD– NOT WHERE IT SHOULDN'T– IN HYPERTENSION

By concentrating its action on the beta-one receptors involved in blood pressure control and to a large extent—at usual therapeutic dosages—avoiding the unwanted effects of beta-two blockade, Lopressor offers potential benefits not available with the nonselective beta blockers.

PHARMACOLOGICAL EVIDENCE FOR SELECTIVITY...

LESS EFFECT ON PERIPHERAL CIRCULATION AFTER EXERCISE[1]
Propranolol, due to beta-two blockade, causes a greater reduction in muscle blood flow than does Lopressor.

REDUCES THE PRESSOR EFFECT OF EPINEPHRINE[2]
Propranolol augments the pressor effect of epinephrine, while Lopressor reduces the pressor effect.

BETTER TOLERABILITY IN PATIENTS WITH ASTHMA[3]
At an antihypertensive dosage (100 mg daily) there was no difference in FEV, and no patients reported any influence on their asthma.

Lopressor should be used with caution in patients with bronchospastic disease. Since beta-one selectivity is not absolute, bronchospastic patients should receive a beta-two-stimulating agent concomitantly. For complete details, see the Warnings section of the prescribing information.

Please see next page for brief summary of prescribing information.

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 100 or less.

Allergic: Pruritus has occurred in less than 1 of 1(patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety c adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effec of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

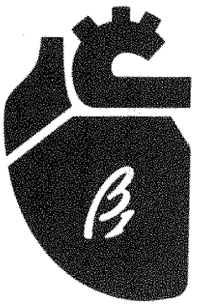
Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.



Dispense in tight, light-resistant container (USP)

667292 C79-22 (8/79)

For complete details, including description, clinical pharmacology and overdosage, please see full prescribing information.

Kinetics of Antifibrillatory Effects of Bretylium: Correlation With Myocardial Drug Concentrations

JEFFREY L. ANDERSON, MD, FACC
EUGENE PATTERSON
MARILYN CONLON
STANISLAW PASYK, MD
BERTRAM PITT, MD, FACC
BENEDICT R. LUCCHESI, PhD, MD

Ann Arbor, Michigan

To determine the kinetics of the antifibrillatory effects of bretylium tosylate and to assess the relative importance of myocardial versus serum drug concentrations, studies were performed in 32 dogs after they received bolus injections of bretylium tosylate (6 mg/kg or 2 mg/kg body weight) or saline solution. Parallel determinations were made of drug concentrations in serum and myocardium, together with antifibrillatory and electrophysiologic effects, both with and without 2 minutes of coronary ischemia produced by temporary coronary ligation. Serum bretylium concentration decreased rapidly after intravenous injection, whereas myocardial concentrations increased gradually, peaking at 1.5 to 6 hours in both open and closed chest dogs. The ratio of myocardial to serum drug concentration increased to 6.4 to 12.6 at 12 hours. Parallel elimination of the drug in serum and myocardium occurred thereafter, with elimination half-life of 10.5 hours (closed chest dogs).

Electrophysiologic and antifibrillatory effects paralleled myocardial rather than serum drug kinetics with peak effects at 3 to 6 hours. The ventricular effective refractory period was 24 to 26 ms greater at 3 hours in dogs treated with the drug than in those receiving saline solution. The ventricular fibrillation threshold increased 6 to 10-fold after 2 mg/kg of the drug was given at 3 to 6 hours in dogs both with and without ischemia in comparison with that in control animals treated with saline solution. The average increase in threshold exceeded 12-fold after administration of 6 mg/kg of the drug (2 minutes to 12 hours). The repetitive ventricular response threshold 3 hours after drug administration increased 5-fold after 2 mg/kg and 18-fold after 6 mg/kg of the drug was administered in dogs with or without ischemia.

These studies elucidate canine serum and myocardial drug kinetics of bretylium, quantify the prolonged antifibrillatory effect of this drug with its delayed maximal effect and emphasize the importance of tissue levels of bretylium in determining drug action.

Rational therapy with antiarrhythmic drugs is predicated on an understanding of pharmacokinetics and mechanisms of action.[1,2] Therapeutic effects depend on drug concentrations at sites of action. In the absence of techniques to determine concentrations at myocardial sites, drug concentrations in blood have been used to estimate expected drug response or adverse effects. However, these correlations may not be valid in drugs heavily concentrated in myocardial tissue, particularly during short-term administration when conditions of equilibrium do not apply.[2]

Bretylium tosylate is an antiarrhythmic drug recently approved for general use in therapy of refractory ventricular tachyarrhythmia.[3,4] Initially introduced more than 20 years ago as an antihypertensive drug, it proved ineffective because of rapid development of tolerance and erratic absorption with oral dosing. Bacaner[5] first discovered its antifibrillatory potential more than 10 years ago, and championed its application as an antiarrhythmic agent.

During short-term administration, bretylium displays a biphasic effect on the cardiovascular system.[6,7] An initial increase in blood pressure accompanied by tachycardia is a manifestation of local catecholamine release at adrenergic nerve endings.[6,8] This is followed by a decrease in blood pressure and relative bradycardia, a manifestation of the drug's antiadrenergic effect. The latter is usually the predominant effect. The electrophysiologic effects of bretylium are complex and their relation to antiarrhythmic effects is as yet unclear.[9,10] The direct antiadrenergic as well as early sympathomimetic effects during administration have all been mentioned as potential contributing mechanisms. An increase in the ventricular fibrillation threshold was described more than a decade ago in dogs treated with bretyllium on a short-term basis,[5] but more recently questions concerning the drugs antifibrillatory as well as its antiarrhythmic effects have again been raised.[4]

The chemical and pharmacologic effects of bretylium place it in a class separate from other currently available antiarrhythmic drugs.[11,12] Studies to date have inadequately elucidated the disposition and mechanism of action of bretylium. Similarly, the onset and time course of antiarrhythmic effect, blood distribution and elimination kinetics and tissue kinetics have not been well defined. A reliable assay for bretylium to allow such studies has heretofore not been available, and a therapeutic range for drug concentrations has not been established.

Recently, a sensitive and reliable gas chromatographic assay for bretylium was developed in our laboratory,[13] which has allowed us to examine several of these questions about the drug's action. Specifically, our purpose was to investigate the time course of antifibrillatory effects of bretylium after bolus injection in dogs, and to correlate the drug's antiarrhythmic effects with both serum and myocardial concentrations. The results confirm the marked antifibrillatory effect of this agent and emphasize the importance of tissue kinetics in determining this behavior.

Methods

Serum and tissue pharmacokinetic studies in open chest dogs: Ten male mongrel dogs weighing 10 to 20 kg were anesthetized with sodium pentobarbital, 30 mg/kg bodyweight intravenously. The left common carotid artery was exposed and cannulated for continuous monitoring of blood pressure. The left external jugular vein was cannulated as an access route for administration of bretylium tosylate. The right femoral vein was also cannulated, and a catheter placed into the inferior vena cava above the level of the renal veins and below the level of the hepatic veins. Percutaneous electrode leads were attached to generate an electrocardiogram for continuous monitoring. The chest was opened with cautery in the fourth left intercostal space and the heart was suspended in a pericardial cradle.

Bretylium tosylate was administered intravenously over 60 seconds in doses of 6 mg/kg (seven dogs) or 2 mg/kg (three dogs). Blood samples (3 ml) were taken for serum bretylium determinations at the following times after injection: 0, 1, 2, 4, 8, 15 and 30 minutes and 1, 2, 4, 8 and 12 hours. Full thickness myocardial tissue samples (50 to 100 mg) were taken with a cylindrical biopsy punch (4 mm in diameter) from the left ventricular free wall at 30 minutes, 90 minutes, 6 hours and 12 hours after drug injection. The dogs were killed at 12 hours, and tissue samples from the left and right ventricles, interventricular septum, anteromedial papillary muscle, mitral valve and atria were taken immediately post mortem for analysis of cardiac distribution of bretylium. Tissue samples were carefully blotted dry, weighed and dissolved in 500 μliters of 16 normal sodium hydroxide. Solutions were neutralized with 800 μliters of 7 normal hydrochloric acid. Solubilized tissue and serum were analyzed for bretylium concentrations using a high resolution gas chromatographic assay recently developed in this laboratory, and sensitive to 1 ng/ml bretylium.[13] Samples were analyzed in duplicate or triplicate and results expressed as μg/ml or μg/g of bretylium free base in serum or tissue, respectively.

Long-term single dose drug kinetics in closed chest dogs: To determine pharmacokinetics in tissue and serum of single dose bretylium in intact animals, six male mongrel dogs weighing 10 to 20 kg were given a single dose of 6 mg/kg of bretylium tosylate intravenously and observed for 48 to 96 hours (median 72 hours). Using a clean surgical technique, we exposed and cannulated the right internal jugular vein with a 9 French catheter introduced while the animal was sedated with sodium pentobarbital (30 mg/kg). Continuous electrocardiographic monitoring (lead II) was used during drug administration and sampling.

The drug was next administered over 60 seconds. Cardiac tissue samples were taken from the right interventricular septum using the Stanford right ventricular bioptome as described by Mason[14] and adapted to dogs. Three to five individual biopsy specimens were taken at each time point, to yield at least 5 mg of myocardial tissue per sample time. Simultaneously, venous blood (3 to 4 ml) was withdrawn for drug assay. After drug injection, tissue and blood samplings were performed at 30 minutes and 3, 6, 12, 24, 36, 48 and 72 hours.

After initial sampling, the dogs were allowed to recover from pentobarbital anesthesia, then reanesthetized lightly each 12 to 24 hours to provide sufficient sedation for subsequent biopsy samplings. Between sampling times, dogs were fed and watered, and allowed free activity in their cages. After the final sampling point, they were killed and tissue samples from the representative myocardial sites earlier noted were taken for confirmation of final myocardial drug concentration and intracardiac distribution of drug. Samples were processed and analyzed as previously described.

Ventricular fibrillation threshold determination: To determine the effect of bretylium on the ventricular fibrillation threshold, 17 male mongrel dogs weighing 10 to 20 kg were given bretylium intravenously in doses of 2 mg/kg (6 dogs) or 6 mg/kg (4 dogs) of the tosylate salt or normal saline solution (7 dogs) over 60 seconds. Serial determinations of the ventricular fibrillation threshold were made.[15,16] Dogs were prepared while sedated with sodium pentobarbital (30 mg/kg). The common carotid artery was isolated and cannulated for constant arterial pressure monitoring using a Statham pressure transducer. The left external jugular vein was cannulated as a venous access site for drug administration. With use of cautery, a left thoracotomy was performed in the fourth intercostal space and the heart was suspended in a pericardial cradle.

A biopolar electrode, consisting of silver-silver chloride electrodes 1 mm in diameter and imbedded in an acrylic plaque, was sewn onto the anterior right ventricle. Electrodes were cleaned daily with emery paper. A pacing electrode was attached to the left atrium using an alligator clip to allow for pacing with a Grass model SD5 stimulator. A plunge bipolar electrode (1 cm in length) was sewn into the surface of the left

ventricle and used to determine the effective refractory period. Lead II of the electrocardiogram was monitored continuously on a Tektronix oscilloscope. The left anterior descending coronary artery was dissected free in its mid portion. A double ligature was passed under the artery and the vessel was temporarily occluded for 2 minutes for the determination of thresholds during ischemia, as noted later. Ventricular effective refractory periods, ventricular fibrillation thresholds (without and with ischemia) and repetitive ventricular response thresholds were all measured in the same series of dogs.

Determination of ventricular fibrillation threshold was performed with a modification of the method of Kroll and Lucchesi.[16] Animals were paced from the atrium at 175 beats/min. Four ms fibrillation pulses of 60 hertz frequency and 200 ms total duration were synchronized to the pacing stimulus with a 50 ms delay, so as to scan the T wave in the vulnerable period of the heart. The current delivered was measured exactly by recording voltage drop across a precision 1,000 ohm resistor in series with the electrodes. Current intensity was increased in 0.5 mA increments to 5 mA, then in 1 mA increments to 10 mA, 2 mA increments to 20 mA and 5 mA increments to 50 mA until ventricular fibrillation developed. Three attempts at each current level were made. The current intensity inducing sustained ventricular fibrillation was defined as the ventricular fibrillation threshold. When fibrillation occurred, the heart was immediately defibrillated using a capacitor discharge direct current defibrillator charged to 10 to 15 joules. The heart was allowed to recover for a minimum of 15 minutes after each determination.

The schedule for determination of ventricular fibrillation threshold was as follows: Before drug administration, a control determination was made in the absence of ischemia. After a 15 minute rest interval, the mid anterior descending coronary artery was ligated and control ischemia threshold determinations were begun after 2 minutes. The ligature was released after fibrillation was precipitated, and the heart was promptly defibrillated. A 30 minute recovery period was allowed and drug or saline solution was administered. Two minutes after injection the threshold was determined; 30 minutes after the drug was given, threshold measurements were repeated; a 15 minute interval was allowed and ischemic threshold was determined. Similar threshold determinations without and with ischemia were made at 90 minutes and 3, 6 and 12 hours after injection. Adequate hydration was provided to maintain blood pressure in the normal range over the 12 hour period of study.

Ventricular effective refractory period and response threshold: Ventricular response threshold was measured at the beginning of each determination of ventricular fibrillation threshold. The ventricular response threshold was defined as the minimal current required to induce a ventricular premature beat in one to three attempts.

The left ventricular effective refractory period was defined as the longest Q-S_2 interval at which a premature impulse (Q-S_2) consistently failed to cause ventricular depolarization; this refractory period was assessed just before each determination of ventricular fibrillation threshold. To make this determination, ventricular extrastimuli (S_2) were introduced after every eight paced sinus beats at two to three times diastolic threshold through a plunge bipolar electrode in the left ventricle. Q-S_2 intervals were reduced by 5 to 10 ms until ventricular capture failed.

Repetitive ventricular response threshold: During the determinations of ventricular fibrillation threshold, the current at which more than two premature complexes were elicited by the fibrillation pulse (during at least one of three trials at a given current level) was defined for purposes of this study as the repetitive ventricular response threshold.

Three to four ml of blood was withdrawn at the time of each threshold determination, to enable comparisons to be made between serum bretylium concentrations and drug effects. Samples were obtained at 2, 30 and 90 minutes and 3, 6 and 12 hours, and analyzed as previously described. Immediately after testing at 12 hours, the animal was killed and a 1 g tissue sample obtained from the left ventricle. Tissue analysis for bretylium was performed as previously noted.

Analysis of data: Electrophysiologic variables and serum and tissue drug concentrations were plotted as mean ± standard error of the mean versus time for each separate group of animals. Drug elimination constants were determined by a linear regression program. Differences in mean responses of two or three groups at a given time were analyzed with Student's *t* test or with analysis of variance for pairwise comparisons.[17] When geometric response in the group receiving 6 mg/kg substantially violated the equal variance assumption (that is, repetitive ventricular response threshold, nonischemic dogs), treatment responses were analyzed independently with use of the *t* test. Paired *t* testing was used to compare response of a given variable in animals under two conditions. Similarity in response of different variables at a given time was sought using a correlation program. Significance was assumed at a probability (p) level of <0.05. For purposes of analysis, a (minimal) ventricular fibrillation threshold of 50 mA was

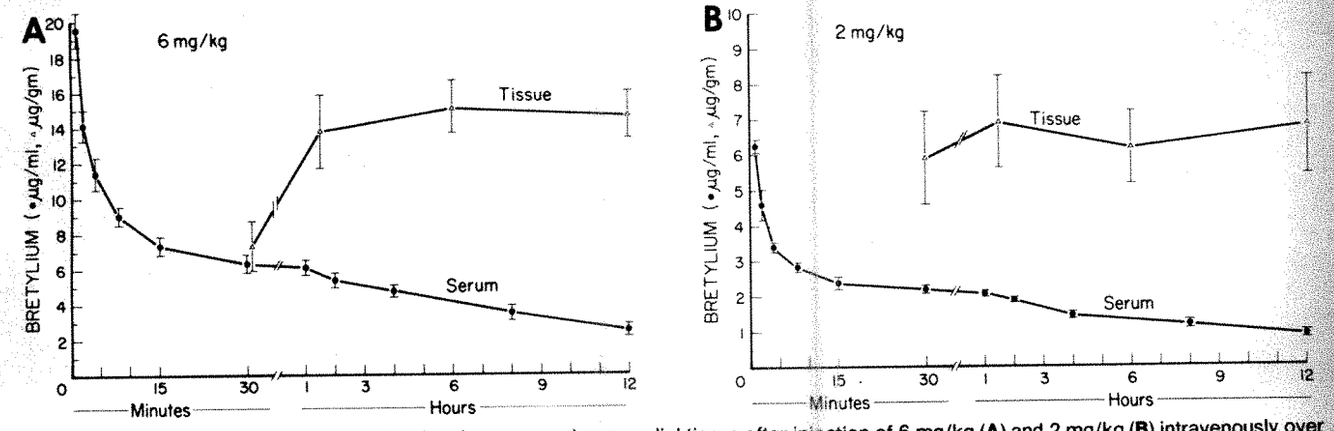

FIGURE 1. Concentrations of bretylium tosylate in serum and myocardial tissue after injection of 6 mg/kg (**A**) and 2 mg/kg (**B**) intravenously over 60 seconds in open chest dogs (seven and three dogs, respectively). Results given as mean ± standard error of the mean.

assigned in instances where the measureable threshold was exceeded.

Results

Serum and tissue bretylium in open chest dogs: After intravenous injection of 6 mg/kg (n = 7) of bretylium tosylate, in seven open chest dogs serum bretylium concentration decreased rapidly along a curvilinear (biexponential) curve from a peak of 19.6 ± 1.1 μg/ml, at 1 minute after injection, to 6.5 ± 0.4 μg/ml at 30 minutes and 2.5 ± 0.3 μg/ml at 12 hours (Fig. 1A). Distribution half-life (t 1/2) was approximately 3 minutes and terminal t 1/2 9.1 hours. Myocardial drug concentration, in contrast, increased progressively with respect to serum drug concentration over the 12 hour period. Tissue bretylium was similar to serum bretylium at 30 minutes (7.3 ± 1.4 μg/g), increased rapidly by 90 minutes (13.7 ± 1.2 μg/g), peaked by 6 hours (15.1 ± 1.5 μg/g) and remained at a plateau elevation at 12 hours (14.6 ± 1.3 μg/g). The ratio of myocardial to serum bretylium increased progressively throughout the study to 1.2 ± 0.3 by 30 minutes and to 6.4 ± 1.0 at 12 hours.

The cardiac distribution of bretylium is shown in Figure 2. At 12 hours significant correlations existed in bretylium concentrations in the left ventricle (14.6 ± 1.3 μg/g), right ventricle (14.3 ± 1.5 μg/g), interventricular septum (14.6 ± 1.6 μg/g) and anteromedial papillary muscle (14.0 ± 1.6 μg/g; $p < 0.01$ for all correlations). Atrial bretylium concentration was slightly although significantly lower (12.2 ± 1.2 μg/g; correlation $p > 0.05$). In contrast, the mitral valve leaflet, a relatively avascular tissue, accumulated bretylium to a concentration of only 2.0 ± 0.3 μg/g.

After injection of 2 mg/kg of bretylium tosylate (three dogs), serum bretylium concentration decreased along a multiphasic curve similar to that for the larger dose (Fig. 1B). Serum bretylium declined from 6.25 ± 0.14 μg/ml at 1 minute after injection to 2.19 ± 0.08 μg/ml at 30 minutes and to 0.87 ± 0.10 μg/ml at 12 hours. Myocardium concentrated bretylium heavily at this dose as well, with tissue bretylium maintaining a plateau of nearly 7 μg/g between 90 minutes and 12 hours. A progressive increase in the ratio was 8.5 ± 2.8.

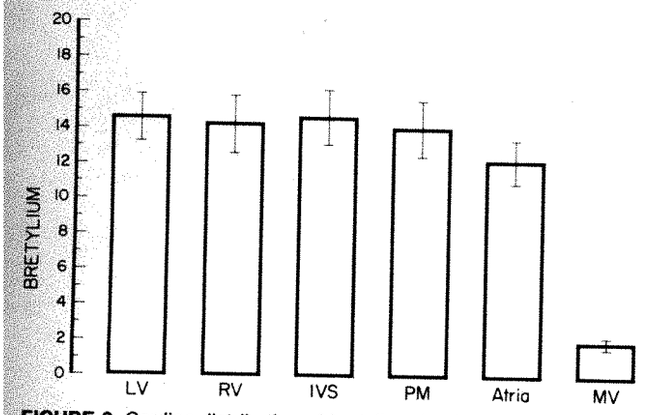

FIGURE 2. Cardiac distribution of bretylium (μg/g) at 12 hours in the seven dogs in Figure 1A. IVS = interventricular septum; LV = left ventricle; MV = mitral valve leaflet tissue; PM = anteromedial papillary muscle; RV = right ventricle. Results given as mean ± standard error of the mean.

Long-term serum and tissue bretylium in closed chest dogs: Serum and myocardial bretylium concentrations measured in closed chest dogs allowed to recover consciousness are presented in Figure 3. Myocardial tissue was obtained by transvenous endomyocardial biopsy from the right interventricular septum in six dogs at various time points after 6 mg/kg of bretylium was injected (see methods). The accuracy of measurements obtained with endomyocardial biopsy samples was confirmed by comparison with larger samples obtained when the dogs were killed. Serum and cardiac bretylium concentrations were similar at 30 minutes (7.15 ± 0.59 and 7.85 ± 0.68 μg/mg, respectively), with a mean tissue to serum ratio of 1.2 ± 0.1. These measurements were also similar to those at 30 minutes in closed chest dogs (Fig. 1A). Serum bretylium then continued to decrease in a nonlinear exponential fashion to 1.35 ± 0.07 μg/ml at 12 hours. This somewhat smaller concentration, when compared with the 12 hour value in open chest given bretylium on a short-term basis, may reflect improved renal excretion in these lightly anesthetized intact animals. Between 12 to 24 and 72 hours, elimination followed a log-linear course, with an elimination rate constant (λ1-s) by linear regression analysis of 0.0663 ± 0.008 $hour^{-1}$, and an elimination half-life from serum (t 1/2-s) of 10.4 hours (harmonic mean).

Myocardial bretylium concentration increased after 30 minutes to peak levels at 3 and 6 hours of 11.3 ± 0.7 and 13.0 ± 2.3 μg/g, respectively. Myocardial concentration of the drug persisted at this high level until 12 hours (11.2 ± 1.6 μg/g), then decreased in parallel with serum bretylium concentration between 24 and 72 hours from 6.25 ± 0.91 to 0.37 ± 0.05 μg/g. Tissue elimination rate constant (λ1-m) between 24 and 72 hours was 0.0662 ± 0.009 $hour^{-1}$, virtually identical to that for serum (λ1-s). Myocardial elimination half-life (t 1/2-m) was 10.5 hours. The ratio of myocardial to serum bretylium in this interval averaged 12.6 ± 1.9 μg/g per μg/ml in the six dogs. These data indicate, in the intact animal, marked myocardial concentration of bretylium, with pseudoequilibrium (parallel elimination) being first established between 12 and 24 hours after single dose injection. Myocardial bretylium was still easily detectable by our assay at 72 hours.

Effects on effective refractory period and response threshold: Bretylium injections caused a time-dependent increase in the left ventricular effective refractory period (Fig. 4). The effective refractory period was unaffected by determination of the ventricular fibrillation threshold, including cardioversion, as shown by the comparability of refractory periods before and after control fibrillation threshold measurement in each group (p = difference not significant). Each of the two control refractory period measurements were also comparable among the three groups. However, after injection of bretylium, significant divergence in response among treated and control groups developed by 90 minutes ($p = 0.007$) and persisted through 12 hours

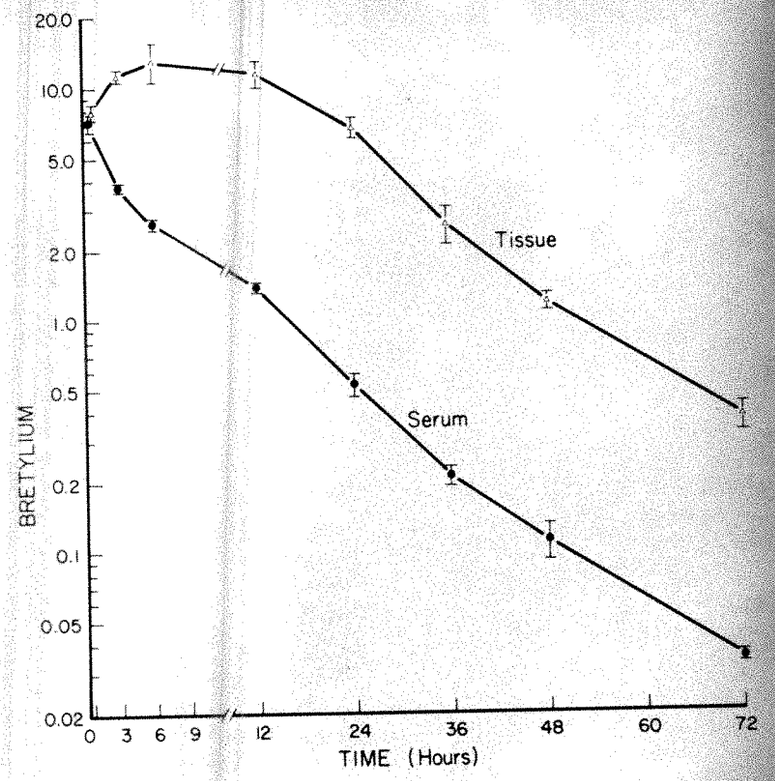

FIGURE 3. Bretylium concentrations in serum (μg/ml) and myocardial tissue (μg/g) in closed chest dogs after bolus injection of 6 mg/kg of the drug. Tissue samples obtained by transvenous endomyocardial biopsy. All six dogs were observed for 48 hours, three for 72 hours and one for 96 hours (point not shown). Values plotted as mean ± standard error of the mean.

($p = 0.046$, analysis of variance). Response after injection of saline solution was flat over time, with mean effective refractory periods of 151 to 153 ms. In contrast, after administration of 6 mg/kg of the drug (four dogs), the refractory period increased from 156 ± 3 at 0 minute and 158 ± 1 at 30 minutes to 171 ± 4 ms at 90 minutes. The peak effective refractory period obtained at 3 hours (177 ± 3 ms) persisted at 6 hours (174 ± 4 ms) and declined (to 164 ± 4 ms) by 12 hours. Increases after administration of 2 mg/kg of the drug (six dogs) were slightly but not significantly less than those after 6 mg/kg, but were significantly greater (90 minutes to 6 hours) than those after administration of saline solution (Scheffe).

Control ventricular response threshold averaged 0.11 ± 0.01 mA (16 dogs), and varied in a fashion similar to effective refractory period. The response threshold was invariant after fibrillation threshold determinations and over the 12 hour study period after injection of saline solution, but tended to increase after administration of bretylium. The peak response threshold occurred at 6 hours, averaging 0.17 ± 0.02 mA after 2 mg/kg and 0.18 ± 0.03 after 6 mg/kg of the drug was given. These changes were not quite significant ($p = 0.05$ to 0.10).

Effects on ventricular fibrillation threshold: Marked increases in ventricular fibrillation threshold developed after injection of bretylium tosylate (Fig. 5). Differences in response among the groups treated with bretylium and the control group treated with saline solution were obviously highly significant from 2 minutes to 12 hours ($p < 0.001$, analysis of variance) (Table I).

At 2 minutes after injection of 6 mg/kg of the drug (nonischemic conditions), ventricular fibrillation could be elicited in two dogs (at 35 mA and 40 mA, respectively) but not in another two dogs (greater than 50 mA) ($p = 0.002$, control time versus 2 minutes). Complete protection from ventricular fibrillation at 50 mA continued thereafter throughout 12 hours of observation in the nonischemic state in all four animals. With 2 minutes of coronary ischemia, the heart of one of four

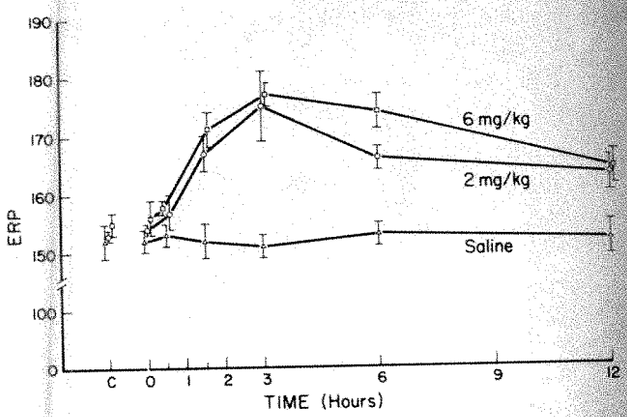

FIGURE 4. Effective refractory period (ERP) plotted in ms ± standard error of the mean versus time. Control time C is before drug administration and initial ventricular fibrillation threshold determination. Control time 0 is after initial determination of fibrillation threshold and directly before drug administration. Other times are 2, 30 and 90 minutes and 3, 6 and 12 hours. Groups include four dogs receiving 6 mg/kg of bretylium, six receiving 2 mg/kg and six receiving saline solution.

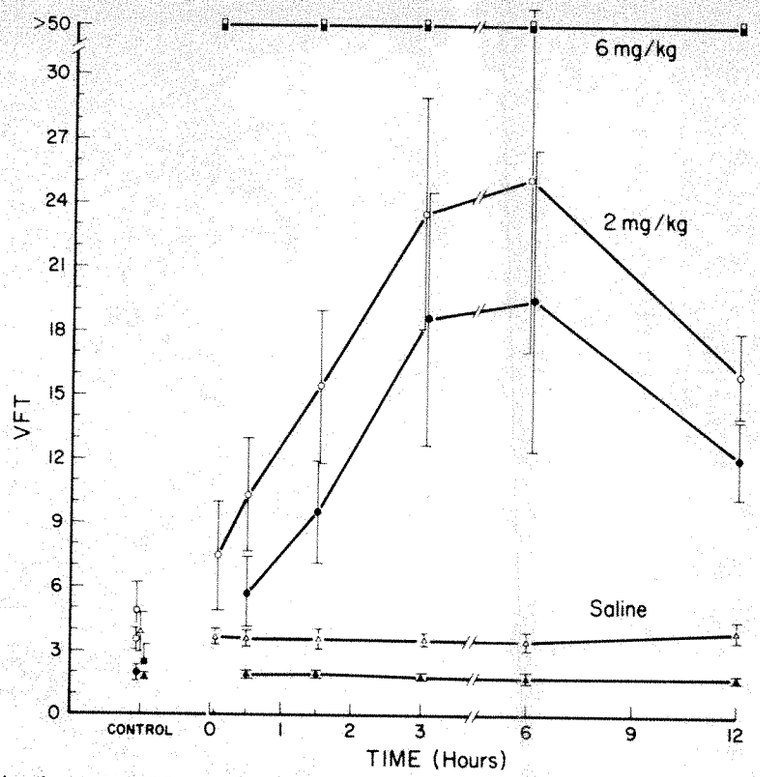

FIGURE 5. Ventricular fibrillation threshold (VFT) response in mA with time after acute injection of 6 mg/kg (four dogs) or 2 mg/kg (six dogs) of bretylium or of saline solution (six dogs). **Open symbols** represent nonischemic and **closed symbols** represent ischemic (2 minutes) conditions (see text). Values are plotted as mean ± standard error of the mean. The control measurement is before drug administration; first measurement after drug administration is at 2 minutes (nonischemic). The mean ventricular fibrillation threshold for the group receiving bretylium is greater than 50 mA, which is above the range of determination. See text for individual variations.

* Individual ventricular fibrillation threshold response is given in milliamperes (mA) at times indicated after drug or saline injection for dogs in groups I to III. For each time, the number to the left of the slash indicates the value without ischemia (NI) and the number to the right of the slash indicates the value after 2 minutes of coronary ischemia (I) (that is, nonischemic/ischemic).

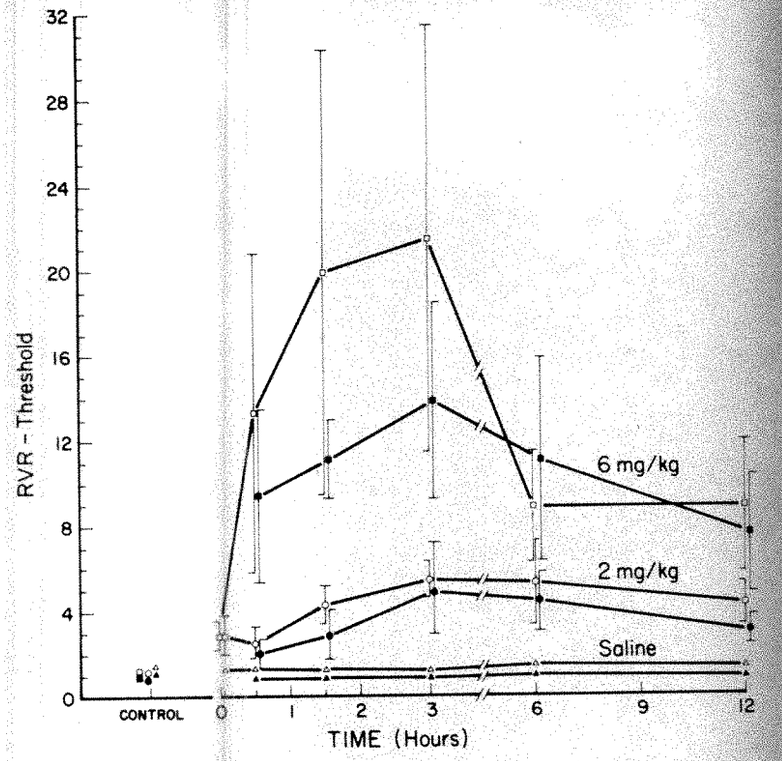

FIGURE 6. Repetitive ventricular response (RVR) threshold (mA) versus time before (control) and after administration of drug or saline solution. Times and number are similar to those in Figure 5. Results are plotted as mean ± standard error of the mean. **Open symbols** indicate nonischemic, **closed symbols** ischemic (2 minutes) conditions. The first measurement after drug administration is at 2 minutes (nonischemic).

dogs could be fibrillated at 30 minutes (at 18 mA); ($p = 0.002$, control time versus 2 minutes) and that of two of four at 12 hours (at 35 mA and 40 mA). For all other determinations, protection from fibrillation despite ischemia was provided to the maximal level, 50 mA impulses.

Increases in ventricular fibrillation threshold also occurred after injection of 2 mg/kg of bretylium salt (six dogs), but these changes fell within the range of determination (Fig. 5). By 2 minutes after-injection, fibrillation threshold had increased from 3.6 ± 0.5 to 7.5 ± 2.5 mA, and by 30 minutes to 10.3 ± 2.7 mA, significantly above control time ($p = 0.03$). The threshold continued to rise in a linear manner to peak at 3 hours (at 23.5 ± 5.4 mA) and 6 hours (25.0 ± 8.2 mA), and decreased somewhat by 12 hours (to 16.0 ± 2.1 mA). Differences between groups treated with bretylium and the group treated with saline solution were apparent from 90 minutes through 12 hours (Scheffe).

The ventricular fibrillation threshold response was similar after ischemia at each time point in the group receiving 2 mg/kg, but thresholds were lower than for nonischemic conditions (Fig. 5). As noted in Methods, each animal served as its own control for ischemic versus nonischemic conditions. The mean threshold during control determination was 2.1 ± 0.4 mA, increased to 5.7 ± 1.7 mA at 30 minutes after drug administration ($p = 0.03$) and further increased to maximal levels at 3 and 6 hours (18.6 ± 5.8 mA, 21.3 ± 8.3 mA, respectively). Some decrease occurred by 12 hours (to 12.0 ± 1.8 mA). Differences between the bretylium-treated and saline-treated groups were significant from 30 minutes to 12 hours ($p < 0.01$, Scheffe).

No change occurred in the fibrillation threshold of the seven control animals receiving saline solution with time in either the ischemic or nonischemic state. This response in control animals verifies the stability of ventricular fibrillation threshold over at least 12 hours in these open chest preparations. The threshold with ischemia (1.7 to 1.9 mA, range of the mean) was approximately half of that without ischemia (3.5 to 4.0 mA, range of the mean) and differed significantly at each timed determination (t test). This finding confirms the deleterious effect of ischemia on ventricular fibrillation threshold.

Effects on repetitive ventricular response threshold: The effect of bretylium on the repetitive ventricular response threshold as defined in Methods is shown in Figure 6. After injection 6 mg/kg of bretylium tosylate in four dogs, the mean response threshold began to increase by 2 minutes (from 1.3 ± 0.3 to 2.8 ± 0.9 mA), peaked at 3 hours (21.4 ± 10.0 mA), then decreased but remained elevated above control values at 12 hours (8.8 ± 3.2 mA). Significant geometric differences between the bretylium-treated and saline-treated groups were present between 30 minutes and 12 hours ($p < 0.003$, t test). After 2 minutes of coronary ischemia, 6 mg/kg of the drug also raised the response threshold so that at 90 minutes it had increased from 1.3 ± 0.4 to 11.1 ± 3.7 mA ($p = 0.01$). The bretylium-treated and saline-treated groups showed differences between 30 minutes and 12 hours (t test). As expected, the absolute elevation during ischemia was generally lower than during nonischemic conditions.

Elevation in repetitive ventricular response threshold of a lower magnitude developed after 2

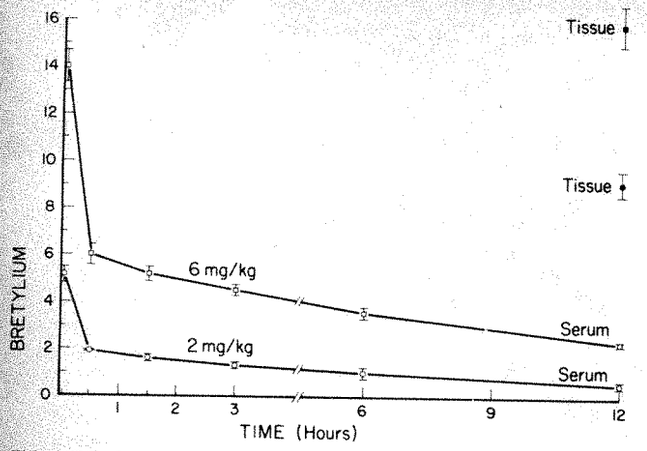

FIGURE 7. Serum (μg/ml) and final myocardial tissue (μg/g) concentrations of bretylium in animals subjected to electrophysiologic testing (Fig. 4 to 6). Results are presented as mean ± standard error of the mean. Compare also with Fig. 1, A and B.

mg/kg of bretylium tosylate. In this group (n = 6) the threshold increased from 1.2 ± 0.2 mA in the control period to 4.0 ± 1.1 mA at 90 minutes (p = 0.03), and to a maximum of 5.4 ± 1.9 mA at 3 hours. Persistent elevation of 4.3 ± 1.0 mA was present at 12 hours. The bretylium-treated and saline-treated groups showed significant differences between 90 minutes and 12 hours (*t* test). Similarly, augmentation in the response threshold occurred in animals treated with 2 mg/kg of the drug after coronary ischemia, with control threshold of 0.8 ± 0.2 mA rising significantly to 2.0 ± 0.6 at 30 minutes (p = 0.03), and further to 4.9 ± 2.0 mA at 3 hours. Elevation persisted at 12 hours (3.0 ± 0.6 mA). The mean values in the saline- and bretylium-treated groups were significantly different from 90 minutes to 12 hours.

The repetitive ventricular response threshold was stable for 12 hours in the control animals injected with saline solution. Repetitive response was elicited at lower current with ischemia (mean 0.7 ± 0.1 mA) than without ischemia (1.5 ± 0.1 mA) (p = 0.03, *t* = 0) (Fig. 6).

Previously proposed as a subfibrillatory measure of ventricular fibrillation threshold, repetitive ventricular response threshold followed the general temporal configuration of fibrillation threshold, although at approximately one fourth the current level. The repetitive response data also suggest a proportionate three- to four-fold greater effect of the three-fold greater dose of bretylium salt (6 mg/kg versus 2 mg/kg). However, in contrast to mean results, the relation of repetitive ventricular response and ventricular fibrillation thresholds in individual animals was too variable to be of much predictive value. Only at 30 and 90 minutes with ischemia (in animals receiving 2 mg/kg) was there an individual correlation of these two thresholds (p = 0.05).

Serum and tissue bretylium in animals tested for ventricular fibrillation threshold: Serial serum concentrations of bretylium measured at the time of ventricular fibrillation threshold determinations for the four animals receiving 6 mg/kg and the six animals receiving 2 mg/kg of the drug are presented in Figure 7. In addition, myocardial (left ventricular) bretylium concentrations at the time the dogs were killed (12 hours) are shown. There is no significant difference between these serum concentration curves and those presented in Figure 1 for the tissue pharmacokinetic study. Tissue levels at 12 hours were likewise similar. Once again, the mean final (12 hour) tissue to serum ratio was greater for the group receiving 2 mg/kg than for the group receiving 6 mg/kg (17.9 ± 3.9 versus 6.9 ± 1.8). It may thus be presumed that the detailed tissue kinetics determined as in Figure 1 apply to the group subjected to ventricular fibrillation threshold determinations.

As expected, a variable (usually modest) increase in blood pressure and heart rate occurred seconds to minutes after drug administration. In all cases, these changes had returned to baseline within 30 minutes. The kinetics of ventricular fibrillation threshold elevation were thus distinct from those of the catecholamine release reaction.

Discussion

Role of myocardial drug concentration in determining therapeutic effects: These kinetic studies emphasize the importance of drug concentrations at tissue sites of action in myocardium in determining therapeutic effects. Whereas serum bretylium concentration decreased rapidly after intravenous injection, both myocardial bretylium concentration and antifibrillatory and electrophysiologic effects increased gradually, peaking at approximately 3 hours. These kinetic results were similar with or without myocardial ischemia and for both doses of bretylium. Bretylium was heavily concentrated in myocardial tissue (6 to 18-fold), suggesting that small changes in serum bretylium at equilibrium might be associated with wide and variable swings in tissue concentration. In addition, conditions of pseudoequilibrium (parallel elimination) in tissue and serum compartments were not obtained until 12 to 24 hours after short-term dosing, as demonstrated in the 72 hour dog model with subsequent elimination half-life in tissue and serum of 10.5 hours. In summary, serum bretylium concentrations after short-term dosing are not predictive of drug effects, whereas an understanding of tissue drug kinetics and concentrations appears to be very useful.

Effect of bretylium on ventricular fibrillation threshold: Bretylium caused marked increases in ventricular fibrillation threshold, confirming its reported efficacy as an antifibrillatory agent.[15,18–20] The canine model used confirms the deleterious effect of ischemia on fibrillation threshold[21] and documents a relatively equipotent therapeutic effect in the ischemic and the nonischemic heart. The responses observed suggest incremental effects on fibrillation threshold of increasing doses of bretylium, in the range tested. Our canine preparation proved to be a highly stable model for threshold determinations over the 12 hour period of observation.

The repetitive ventricular response threshold was a useful predictor of group response of ventricular fibrillation threshold to drug. However, in the individual animal, the correlation was too variable to be useful. In general, at least a proportionate rise in antiarrhythmic effect is predicted by the repetitive ventricular response as the dose is increased from 2 to 6 mg/kg. The data on repetitive ventricular response also suggest that peak drug effect after 6 mg/kg, similar to that of a smaller dose, occurs at approximately 3 hours.

The time course of change in effective refractory period was similar to that for ventricular fibrillation and repetitive response thresholds. However, increases in refractory period were not proportionate to increases in drug concentration. The parallel temporal change of effective refractory period and fibrillation threshold suggests a correlation between drug effect on effective refractory period and on fibrillation threshold. On the other hand, incremental change in refractory period using 6 mg/kg in comparison with 2 mg/kg was much less than that for fibrillation threshold. These observations suggest a nonlinear relation between these two measures of drug effect or the importance of factors in addition to changes in refractory period in determining ventricular fibrillation threshold.

These studies demonstrate the utility of endomyocardial biopsy in allowing long-term observations of drug kinetics in myocardial tissue. Information derived may be particularly useful for clinical comparisons. Our observations confirmed the long persistence of drug in myocardium after single dosing, with detectable drug persisting for more than 72 to 96 hours.

Mechanism of bretylium's cardiac effects: Controversy continues to exist as to whether bretylium has important direct effects on the human heart independent of its action on the adrenergic neuron.[3,4] Experimental work suggests that both direct electrophysiologic effects and myocardial concentration of drug are independent of cardiac nerves.[8,22,23] Cardinal and Sasyniuk[9] showed that bretylium increases action potential and refractory period duration in isolated Purkinje fibers, and reduces the disparity in local action potential duration between normal and infarct preparations. Namm et al.,[22] using immunosympathectomized rats, showed the marked myocardial concentrations of bretylium to be independent of cardiac sympathetic nerve uptake. Electrophysiologic effects, including lengthening of effective refractory period and action potential duration, were also similar in both normal and immunosympathectomized animals. Bretylium was found to bind to cell plasma membranes in a tight but reversible fashion. Our observations lend support to those of these workers, and suggest that the kinetics of electrophysiologic and antifibrillatory effects of bretylium parallel those of drug accumulation in myocardial tissue. In contrast, the kinetics of catecholamine release and serum drug are dissimilar.

Serum versus myocardial drug kinetics: Detailed studies of myocardial tissue kinetics of other antiarrhythmic drugs have not come to our attention. The relation between serum drug kinetics and drug action after short-term administration varies among these agents. With drugs such as lidocaine, a direct temporal relation appears to exist. Schnittger et al.[24] demonstrated a linear relation between plasma lidocaine concentrations during acute infusions and increases in ventricular fibrillation threshold. With other drugs such as bretylium, acute effects are dissociated from blood kinetics and maximal effects may be substantially delayed. The antiarrhythmic effect of amiodarone does not become evident until 4 to 8 days after therapy is begun.[25] Intravenous propranolol may yield immediate therapeutic benefit, but plasma concentrations do not correlate simply with drug effects.[25] Lameijer and van Zweiten[27] found slow (1 to 3 hours), 10-fold concentration of quinidine in the isolated mammalian heart and parallel temporal changes in refractory period. Strauss et al.[28] found procainamide to be concentrated in myocardium in a ratio of 2.3:1, after a 4 hour loading infusion, but kinetics were not studied. Further studies of myocardial tissue kinetics of these drugs would be of interest.

Clinical implications: Our study in dogs demonstrates marked time- and dose-dependent differences in response to bretylium tosylate. Clinical extrapolation of these data as in other animal studies must be tentative. However, clinical implications might include the need for repeated acute drug dosing and allowance of greater time after acute bretylium administration before assuming drug failure. Current package insert recommendations reflect this implication.[29] Thus, if the initial 5 mg/kg bolus injection of bretylium is ineffective in restoring rhythm, additional dosing up to 30 mg/kg total over about 30 minutes is suggested.[29] The delayed response in ventricular fibrillation threshold rise seen with our small dose might thereby be converted to an immediate response similar to that seen with our larger dose (Fig. 5). This study confirms the utility and sensitivity of a new drug assay for bretylium using a gas recently described chromatographic method.[13] A more rational approach to administration of bretylium in patients should result from clinical application of this assay and further testing of the inferences suggested by this study.

Myocardial Effects of Long-Term Cigarette Smoking: Relative Roles of Carbon Monoxide and Nicotine

S. SULTAN AHMED, MD, FACC
CHRISTOS B. MOSCHOS, MD, FACC
HENRY A. OLDEWURTEL
TIMOTHY J. REGAN, MD, FACC

Newark, New Jersey

In a prior study of an animal model exposed to long-term cigarette smoking, left ventricular performance was observed to decline in association with morphologic evidence of collagen accumulation. Because controversy has existed as to whether nicotine or carbon monoxide is the major pathogenetic agent in cigarette smoking, 18 young adult male beagles with chronic tracheostomy were placed in three groups of six dogs each: Group 1 served as a control group; group 2 received seven cigarettes of low nicotine content (0.2 mg/cigarette), which effected a peak carboxyhemoglobin level approximating 5/100 ml, similar to that of regular cigarettes; and group 3 received nicotine twice daily intramuscularly in an amount equivalent to seven cigarettes/day. In the intact anesthetized state, heart rate, left ventricular end-diastolic pressure and volume (indicator dilution) did not differ among the three groups. To assess relative myocardial wall stiffness, saline solution was infused into the left ventricular chamber. A significantly higher end-diastolic pressure and tension were elicited in group 3, suggesting a decrease in left ventricular compliance. No such change was observed in either group 1 or 2. Only long-term nicotine use was associated with increased hydroxyproline content in the left ventricular myocardium, suggesting a basis for enhanced stiffness. An index of left ventricular contractility was derived from the peak rate of rise of left ventricular pressure (dP/dt), normalized for preload and afterload. Groups 1 and 2 showed no difference in this index (2.18 ± 0.3 versus 2.15 ± 0.18 muscle lengths/s per cm) at similar levels of aortic pressure, but the index was significantly lower (1.28 ± 0.12, $p < 0.01$) in group 3. Thus, the effects of long-term cigarette use on the myocardium appear to be predominantly dependent on nicotine rather than on carbon monoxide.

Although several epidemiologic and pathologic studies[1,2] have suggested an increased incidence of cardiovascular disease among persons who smoke, a direct causal relation between long-term smoking and cardiac disease has not been established. In a previous study of an animal model,[3] the effects of long-term smoking and nicotine administration were observed to produce functional and morphologic abnormalities of the left ventricle consistent with the view that habitual smoking has an effect on the myocardium independent of coronary artery disease. The toxic effects of smoking were considered largely dependent on the nicotine content of cigarettes.

Carboxyhemoglobin levels similar to those found in heavy smokers have been reported to accelerate atherosclerotic changes and induce myocardial damage in animals. Carbon monoxide, and not nicotine, was therefore considered the major toxic component responsible for the increased risk of cardiovascular disease.[4] To test the latter assumption this study was undertaken to determine the relative alterations of myocardial function and composition in an animal model as a response to long-term carbon monoxide or nicotine use.

Methods

Experimental preparation: To assess the relative roles of nicotine and carbon monoxide as the major pathogenetic agent in the development of heart muscle disease due to long-term cigarette smoking, 18 month old littermate male beagles were prepared with a permanent tracheostomy. They were alternately placed into three groups of six dogs each: group 1, a control group; group 2, dogs

smoking daily seven cigarettes with negligible nicotine content; and group 3, dogs receiving intramuscularly doses of nicotine previously shown to mimic the left ventricular responses to cigarette smoking.[3]

Smoking in group 2 was performed by the method of Cahan and Kirnan.[5] The cigarettes were a commercial brand (Sano) without filters and contained only 0.2 mg nicotine/cigarette. The smoking was done in two sessions each day. In group 3 (nicotine users), 210 μg/kg of nicotine was injected intramuscularly twice a day. This dose was considered approximately equivalent to that observed in beagles that have smoked seven cigarettes containing 1.35 mg of nicotine/cigarette.[3]

Body weight, hematocrit, serum proteins and electrolytes were monitored throughout. At the end of the 18 month study, the dogs were anesthetized with morphine sulfate (3 mg/kg body weight) and sodium pentobarbital (15 to 20 mg/kg) 18 hours after eating and were placed in the right lateral position. After insertion of a cuffed endotracheal tube, respiration was regulated with a Harvard respiratory pump. This procedure facilitated the maintenance of arterial pH and partial pressures of oxygen and carbon dioxide in the normal range.[3]

Hemodynamic measurements: For pressure measurements an 80 cm 8F National Institutes of Health catheter was passed through the right carotid artery into the left ventricular chamber. From the left carotid artery, a 55 cm 8F National Institutes of Health catheter was placed in the aortic root, 1 to 2 cm above the aortic valve. A 50 cm 7F Swan-Ganz catheter was passed through the jugular vein into the pulmonary artery and a small polyethylene catheter (PE) into the femoral vein. Statham transducers were used for the measurement of left ventricular (P23Gb) and aortic (P23Db) pressures. These were placed at the mid thoracic level and balanced for equal sensitivity. The maximal rate of rise of left ventricular pressure (dP/dt) was obtained using the resistance-capacitance differentiating circuit. Systolic ejection period was measured from superimposed aortic and left ventricular pressure pulse tracings. The frequency response of this system is linear from 0 to 30 cycles/s. End-diastolic pressure was measured over at least two respiratory cycles and averaged. This measurement has been found to correlate to a high degree with the pressure measurement obtained using a micromanometer tip (Millar®) catheter in accord with previous studies.[6,7] Cardiac output was measured from the indicator-dilution curves sampled from the pulmonary artery after right atrial injection.[8,9] Three successive curves were used to calculate the forward flow. Stroke volume and stroke work were obtained as previously reported.[6]

Left ventricular ejection fraction was measured by indicator-dilution technique using cold saline solution rapidly injected into the left ventricle.[10] The thermistor for the ejection fraction was placed into the National Institutes of Health catheter, 1 to 2 cm above the aortic valve. Three or four such curves were obtained and end-diastolic volume was calculated as a ratio of mean stroke volume to mean ejection fraction.[11] Left ventricular ejection fraction obtained with this technique has shown good reproducibility in a model under nearly ideal conditions of mixing and sampling (mean coefficient of variation 3 percent).[11] Whereas the injection artifact appears to be negligible with the indicator-dilution method, angiographic dye can produce sustained depression of ventricular function, especially in the abnormal heart.[12] Despite a systematic difference between the two techniques, there is a good correlation of the ejection fraction that is derived from the indicator-dilution and angiographic techniques (correlation coefficient 0.824).[13]

The angiographic technique has yielded systematically lower values for end-diastolic volume than has the indicator-dilution method (averaging 13 percent lower in the study of Hugenholtz et al.[13] [correlation coefficient 0.96]). Although an absolute test of accuracy in vivo is not available, two additional studies[14,15] comparing the indicator-dilution technique with independent methods have shown good agreement. The latter study represents a revision of a previous conclusion that the indicator-dilution technique differs substantially from angiographic data.[16] For these reasons the indicator-dilution method was the primary technique used in this study. The dilution curves, pressures, left ventricular maximal dP/dt and electrocardiogram were recorded on an Electronics for Medicine DR-8 recorder.

Left ventricular function and contractility were estimated in several ways. Contractility was assessed in the intact animal from an index expressing the end-isometric force-velocity relation normalized for initial fiber length. This contractility index exhibits a relatively narrow range in normal ventricles, increases in a predictable fashion with positive inotropic interventions and is depressed in the presence of left ventricular disease.[17] The formulation includes $(dP/dt\ max/MIP)/2\pi r$, where dP/dt max is the maximal rate of rise and left ventricular pressures in mm Hg/s, MIP the maximal isovolumetric pressure in mm Hg, and $2\pi r$ the end-diastolic left ventricular circumference in cm.[17] The units of contractility are muscle length/s per cm of initial circumferential fiber length. The left ventricular radius was calculated from end-diastolic volume on the assumption that the ventricle was a sphere at the end of the isovolumetric period, and circumferential fiber length was calculated as $2\pi r$. Another index expressing the myocardial contractility used in this study was velocity of contractile element (V_{ce}) at peak dP/dt, calculated as the ratio of maximal dP/dt for simultaneous left ventricular pressure in accord with the method of Levine and Brittman.[18]

Left ventricular function was further assessed during volume expansion.[6] A second catheter was introduced into the left ventricle, and saline solution at the temperature of blood was infused at 48 ml/min for 3 to 5 minutes. During the saline infusion, end-diastolic pressure was continuously recorded at high sensitivity and the cardiac output and ejection fraction were determined immediately after 3 minutes of infusion when the animals were in a steady state as judged from heart rate, aortic pressure and ventricular end-diastolic pressure.

To determine if ventricular pressure increments during volume expansion are at least partially affected by enhanced intrapericardial pressure,[19] *three normal dogs were assessed in the intact anesthetized state.* A catheter was introduced into the pericardial space by a modification of the transseptal technique utilizing a small Odman-Ledin catheter and a Brockenbrough needle (infant size).[20] By this technique the catheter is advanced over the needle into the pericardial space after the latter penetrates the free wall of the right ventricle. To determine ventricular end-diastolic transmural pressures, catheter tips were located within the chest using the posteroanterior chest X-ray films taken at each stage of the study with correction made as necessary for magnification. Statham pressure transducers (P23Db) were placed at the level of the spine and circulatory and pericardial pressures were corrected to this reference level by subtraction or addition of 1 cm water for each centimeter of height; the respective catheter tip was above or below this level. Ventricular end-diastolic and pericardial pressures were recorded at high sensitivity (1 mm Hg equal to 4 mm paper) and were measured at end-expiration and by using averaged pressure levels throughout three respiratory cycles.

After infusion of normal saline solution at 50 ml/min into the left ventricular chamber for 4 minutes, intrapericardial end-diastolic pressure was -1 ± 0.6 mm Hg (mean ± standard

AoD, AoS = aortic diastolic and systolic pressures, respectively (mm Hg); Cylx = Frank-Levinson index of contractility (muscle lengths/s per cm); dP/dt = first derivative of left ventricular pressure (mm Hg/s); EDP = left ventricular end-diastolic pressure (mm Hg); EDV = left ventricular end-diastolic volume (ml/kg); EF = ejection fraction (percent); HR = heart rate (beats/min); NS = not significant; p = probability; SV = left ventricular stroke volume (ml/kg); SW = left ventricular stroke work (g-m/kg); TSR = total systemic resistance (dynes s cm^{-5}); V_{ce} = velocity of contractile element at peak dP/dt (muscle lengths/s); wt = body weight (kg).

error of the mean) compared with the control value of −2 ± 0.7 mm Hg, a nonsignificant change. Moreover, sampling of right heart blood before and after 4 minutes of saline infusion revealed no decrease in hematocrit or serum albumin, implying that much of the solution diffused out of the vascular system without recirculation in this time span. Thus, the filling pressure responses in the beagle during infusion of a proportionate amount of saline solution into the left ventricle are considered to be largely independent of intrapericardial pressure.

Electrophysiologic studies of left ventricular conduction were also performed, usually before the hemodynamic studies by an electrocatheter technique in accord with Ettinger et al.[21]

Myocardial histology: At the conclusion of these studies, the heart was rapidly arrested with iced Ringer' solution. Samples of the left ventricle, approximately 15 g, were taken from the periapical region for analysis of cation and myocardial lipids.[3] Sections were also taken from the left ventricular myocardium and left coronary artery for histochemical and microscopic studies by the pathologist without knowledge of identification.[3]

Because the myocardium of long-term smoking beagles has been found to accumulate collagen,[3] the presence of collagen was quantified by measuring the myocardial content of hydroxyproline.[22]

Statistical analyses: These were performed using conventional methods for small samples and variation reported as standard error. Differences between groups were evaluated with Student's unpaired *t* test. The *t* test for paired samples was used to evaluate the response to saline infusion within each group. Values are expressed as mean ± standard error of the mean.

Results

Nutritional state and blood chemical values: The dogs in group 1 (control group) and group 3 (nicotine users) behaved similarly to those reported on in our prior study.[3] In contrast to the control dogs, dogs in the two experimental groups did not gain weight during the observation period, but there was no statistical difference in weight among the three groups at the conclusion of the study. (Table I). The final indexes of nutritional state were comparable to initial values in the three groups. The final hematocrit levels were 39 ± 2, 38 ± 3 and 42 ± 1 percent, respectively, in groups 1, 2 and 3. Serum albumin levels were 3.8 ± 0.2, 3.6 ± 0.1 and 3.0 ± 0.8 g/100 ml in the respective groups. Serum potassium and sodium values (in mEq/liter) were 3.3 ± 0.3 and 3.2 ± 0.2, 4.8 ± 0.8 and 145 ± 1, and 140 ± 4 and 137 ± 6, respectively. No group exhibited changes in plasma levels of triglycerides, free fatty acids, phospholipids or cholesterol. The final values for serum triglycerides (mol/liter) and free fatty acids (μEq/liter) were 0.34 ± 0.08 and 0.34 ± 0.08, 0.35 ± 0.12 and 300 ± 35, and 292 ± 36 and 296 ± 40 in the three groups. Serum phospholipids and cholesterol values (mmol/liter) were 2.47 ± 0.31 and 2.54 ± 0.60, 1.86 ± 0.18 and 3.16 ± 0.31, and 3.59 ± 0.96 and 2.16 ± 0.96.

Carboxyhemoglobin: In group 2 (smokers) smoking three cigarettes, either of low nicotine content such as that in Sano or of high nicotine content as in a regular cigarette, over 30 minutes resulted in similar amounts of carboxyhemoglobin in the dogs in both the immediate and the late periods (Fig. 1). The carboxyhemoglobin values in g/100 ml after smoking three cigarettes of regular or low nicotine content were, respectively, 5.5 ± 1.0 and 4.9 ± 0.9 at 5 minutes, and 1.1 ± 0.1 and 1.8 ± 0.9 at 18 hours.

Hemodynamics and left ventricular contractility: The resting hemodynamic values in the three groups are shown in Table I. Compared with groups 1 and 2, the dogs receiving nicotine became hypertensive and had significantly higher values for systolic and diastolic pressures as well as peripheral resistance. There were no significant differences in pressure between groups 1 and 2. Heart rate, stroke volume, left ventricular end-diastolic volume, end-diastolic and pulmonary arterial pressures did not differ significantly among the three groups.

The ejection fraction in the dogs receiving nicotine (group 3) was reduced to 24 percent compared with 37 and 38 percent, respectively, in groups 1 and 2 (each p

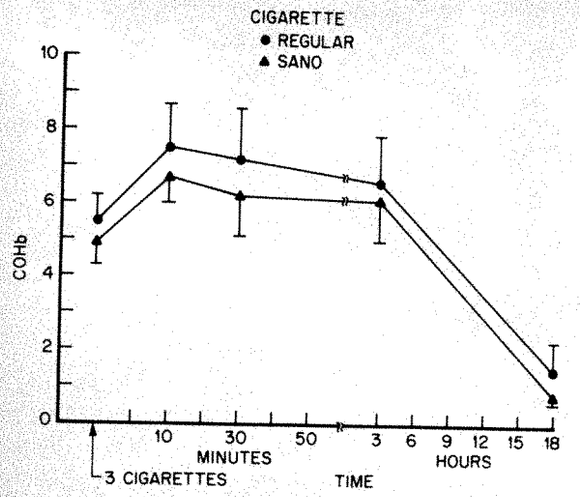

FIGURE 1. Carboxyhemoglobin (COHb) levels in dogs after smoking three cigarettes of regular or low (SANO) nicotine content in 30 minutes. These levels are similar in the two groups both during and 18 hours after smoking.

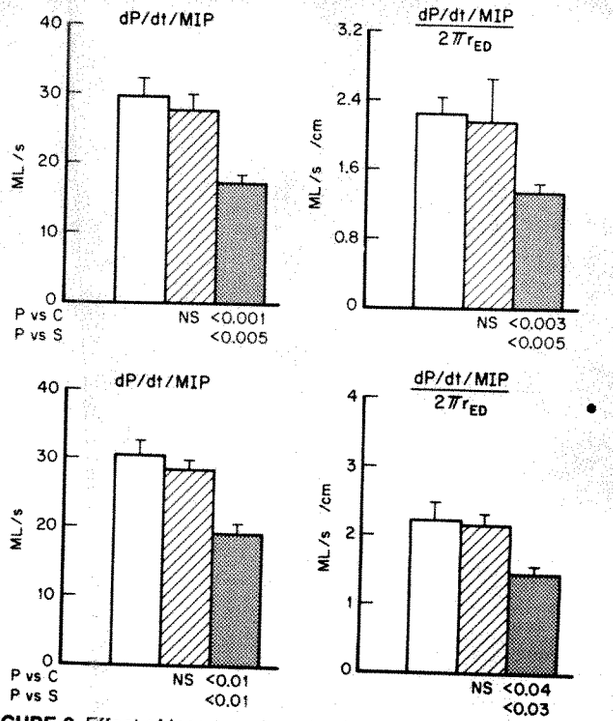

FIGURE 2. Effect of long-term low nicotine cigarette smoking (group 2 [S] **hatched bars**) and nicotine administration (group 3, **dotted bars**) on the indexes of left ventricular contractility and data in control dogs (group 1 [C] **open bars**) (**top**) and in three dogs from the two experimental groups with aortic pressure matching those in three control dogs (**bottom**). C = control group; dP/dt = rate of rise of left ventricular pressure; MIP = maximal isovolumic pressure (mm Hg); ML = muscle length; NS = not significant; P = probability; 2πrED = end-diastolic circumference (cm).

<0.001). Similar to the reduction in systolic performance characteristics, only the dogs receiving nicotine exhibited a deficit in the contractile function of the left ventricular muscle. This function was preserved in group 2, smoking low nicotine cigarettes. The contractility index in group 3 was 1.28 muscle length/s per cm compared with 2.18 in the control group and 2.15 in the smoking dogs ($p < 0.001$). The more readily measured index of contractility (namely, the velocity of contractile element of peak isometric stress (V_{ce}), which is not corrected for end-diastolic fiber length) also showed a similar reduction, 17.7 muscle lengths/s versus 30 and 28, respectively, in groups 1 and 2 ($p < 0.001$); no difference was noted between groups 1 and 2 (Fig. 2, top).

There was no correlation of the aortic pressure level and the indexes of left ventricular contractility. This was evidenced in three dogs from each group with similar levels of aortic diastolic pressure. The contractile deficit was still evident in the dogs receiving nicotine, even though the pressure was at approximately the same level as in the other two groups (Fig. 2, bottom). It thus appears that the contractile deficit is independent of increased afterload. To assess relative wall stiffness, saline solution was infused into the left ventricular chamber. A significantly higher end-diastolic pressure and tension was elicited in the dogs receiving nicotine, suggesting a decrease in left ventricular compliance; no such change was observed in either group 1 or 2 (Fig. 3).

Intracardiac conduction: To determine whether the reduced contractility may have been at least in part related to a delay in spread of excitation to the conduction fascicles and myocardium, His bundle electrograms were performed on the left side. All the intracardiac times in all dogs were essentially similar, indicating no gross delay of conduction through the myocardium of those receiving nicotine. The P-H times (ms) in groups 1 to 3 were, respectively, 71 ± 5, 66 ± 4 and 63 ± 5. The respective H-Q times (ms) were 27.6 ± 2.5, 26.8 ± 1.5, 30 ± 2.5; and the values for QRS duration (ms) were 57 ± 3, 60 ± 5 and 50 ± 5.

Myocardial pathology: At the conclusion of this study, the weight of the left ventricle and septum in g/kg of total body weight was 4.4 ± 0.4, 4.7 ± 0.4 and 5.4 ± 0.8 in groups 1, 2 and 3, respectively. On gross examination, the coronary arteries were normal, no visible intimal lesions were noted in any group.

The sole consistent morphologic abnormality on light microscopy consisted of collagen accumulation seen in the trichrome stain in group 3; there was no hypertrophy or inflammation. The presence of this collagen was confirmed by chemical analysis in the left ventricular wall. The hydroxyproline level was significantly increased in the left ventricular myocardium in the group receiving nicotine (6.61 ± 0.31 μg/mg dry weight versus 5.51 ± 0.11 and 5.8 ± 0.17 in groups 1 and 2, respectively) (Fig. 4). The myocardial composition of the lipid classes and major cations did not differ significantly in the three groups (Table II).

Discussion

Role of carbon monoxide: Carboxyhemoglobin levels similar to those found in heavy smokers have been reported to cause atherosclerotic changes and myocardial damage in animals.[23] Carbon monoxide is therefore considered a toxic component and has been postulated

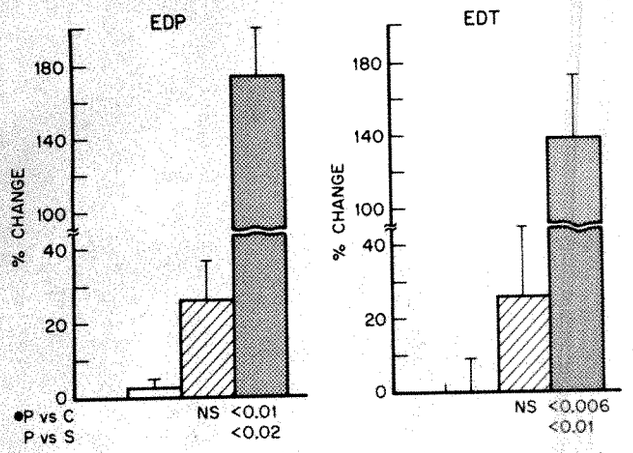

FIGURE 3. Changes (expressed as percent changes from preinfusion value) in end-diastolic pressure (EDP) and tension (EDT) after saline infusion, indicating a decrease in left ventricular compliance in animals receiving nicotine. **Open bars** = control dogs (group 1); **hatched bars** = low nicotine cigarette smokers (group 2); **dotted bars** = dogs receiving nicotine (group 3).

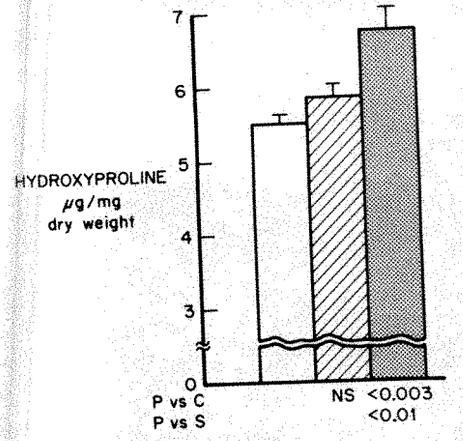

FIGURE 4. Collagen content of left ventricular myocardium expressed as hydroxyproline in three groups. Significantly increased levels are noted only in the dogs receiving nicotine (group 3). **Bars** as in Figures 2 and 3.

to have a major role in the cardiovascular disease due to long-term cigarette use.[4] An important basis for this current study is the observation that similar levels of carboxyhemoglobin result after smoking cigarettes with high, low or no nicotine content.[24] Because increases in systolic blood pressure and heart rate occur only after smoking nicotine-containing cigarettes, the acute hemodynamic responses appear to be independent of carbon monoxide.[25]

In this study we found that carboxyhemoglobin did not differ among beagles smoking three cigarettes of low or high nicotine content, either in the immediate postsmoking or late period (Fig. 1). In dogs smoking low nicotine cigarettes for 18 months there were no abnormalities of myocardial performance or composition.

Role of nicotine: In contrast, the group receiving nicotine exhibited a significant decrease in diastolic compliance during volume expansion compared with control animals. The decrease in left ventricular diastolic compliance appears to be related to the increased collagen content of the myocardium in the animals receiving nicotine. On the basis of separate studies of pericardial pressure during saline infusion, the pericardium was not considered to contribute to the decrease in ventricular distensibility, a finding supported by a recent study.[26]

The nicotine users were also characterized by a decrease in the contractility indexes in the basal state. Aortic pressure was elevated in this group and can reduce ventricular performance. However, there was no correlation between the level of aortic pressure in the dogs receiving nicotine and depression of indexes of left ventricular contractility. This was most evident in three dogs from each of the three groups, with similar levels of diastolic pressure (Fig. 2, bottom). Moreover, in a prior study aortic pressure was increased with angiotensin in the normal animal to the same levels as noted in animals receiving nicotine by infusion of angiotensin.[3] No reduction in the variables characterizing myocardial function was noted. Furthermore, in the early stages of chronic hypertension in man, ventricular performance is not uniformly diminished.[27] This would indicate that the reduction in ventricular performance by nicotine was not dependent on afterload. Ischemia does not appear to contribute to these abnormalities, because the coronary arteries were free of intimal disease and the myocardial cation content did not differ from that of control animals.

TABLE II

Myocardial Lipids and Cations at 18 Months in Three Groups of Dogs (mean ± standard error of the mean)

	Group 1 (control)	Group 2 (smokers of low nicotine cigarettes)	Group 3 (nicotine users)	p Values (2 vs 1, 3 vs 1, 3 vs 2)
LV wt	4.4 ± 0.4	4.7 ± 0.4	5.4 ± 0.8	NS
Trig	2.4 ± 0.8	2.3 ± 0.4	1.4 ± 0.8	NS
FFA	8.0 ± 0.6	6.7 ± 0.7	7.6 ± 0.6	NS
Phospho	24.8 ± 0.9	21.2 ± 1.9	21.1 ± 0.8	NS
Chol	5.31 ± 0.27	5.30 ± 0.14	4.55 ± 0.35	NS
Na	46 ± 4	44 ± 3	42 ± 4	NS
K	71 ± 2	66 ± 4	66 ± 5	NS
H_2O	79 ± 1	79 ± 1	80 ± 0.9	NS

Chol = cholesterol (μmol/g wet weight); FFA = free fatty acids (μEq/g); H_2O = water (percent); K = potassium (μEq/g wet weight); LV wt = weight of left ventricular septum (g/kg); Na = sodium (μEq/g wet weight); NS = not significant; p = probability; Phospho = phospholipids (μmol/g); Trig = triglycerides (μmol/g).

Myocardial changes: In this study, increases in collagen on chemical analysis were present only in the group receiving nicotine. This may be a result of increased synthetic activity of the fibroblasts in the interstitium as a result of long-term exposure to a sufficient quantity of nicotine. A limitation to velocity of contraction produced by associated changes in the elastic properties of myocardium may be responsible for the contractile deficit.[28] Although a direct effect of nicotine on the contractile mechanism by means of altered calcium mobilization has not been observed in short-term studies,[29] calcium fluxes have not been evaluated in long-term experiments.

Serum and myocardial lipids: Serum lipids were not changed in either the long-term smokers (group 2) or the group receiving nicotine, a finding that might have been altered by a high lipid diet. However, increments in serum cholesterol are reported to occur after administration of nicotine at higher dose levels than that of our study.[30] The normal myocardial lipid levels contrast with those of experimental alcoholism[6] and diabetes.[31] In these states, interstitial collagen accumulation is associated with enhanced triglyceride levels in cardiac cells. Altered myocardial composition after long-term cigarette use has previously been inferred from a morphologic study.

Implications: The cardiovascular responses of long-term nicotine administration in the beagle closely paralleled previous observations[3] in animals smoking regular cigarettes for many months but were in contrast to findings in the dogs in this study smoking low nicotine cigarettes. Thus it appears likely that the long-term effects of cigarette smoking on the myocardium are predominantly dependent on nicotine rather than on carbon monoxide.

Electrophysiologic Effects of Imipramine and Doxepin on Normal and Depressed Cardiac Purkinje Fibers

F. JAMES BRENNAN, MD, FACC

Kingston, Ontario, Canada

The tricyclic antidepressant drug imipramine may cause ventricular arrhythmias and intraventricular conduction disturbances in clinical use, particularly in patients who have ingested toxic doses or who have preexisting heart disease. Such effects have not been reported with doxepin, another tricyclic antidepressant drug. In this study, the electrophysiologic effects of these two drugs on normal and depressed canine Purkinje fibers were examined. Fiber depression was achieved by elevating potassium concentration [K^+] in the perfusate to 10 m*M*. In normal Purkinje fibers both imipramine and doxepin were tested in concentrations of 50, 250, 500 and 1,000 ng/ml. Both drugs had no effect on resting membrane potential but caused similar, dose-related reductions in action potential amplitude, maximal velocity of phase 0 depolarization ($\dot{V}_{max}$), action potential duration, conduction velocity and effective and functional refractory periods. Depressed fibers were exposed to only 250 ng/ml of imipramine and doxepin. Both drugs reduced conduction velocity and failed to alter the refractory periods of the depressed fibers whereas at the same concentration in normal fibers they caused no change in conduction velocity but shortened the refractory periods. The other electrophysiologic effects of the two drugs on depressed fibers were similar to those on normal fibers. These observations indicate that depressed fibers are more sensitive than normal fibers to certain electrophysiologic effects of both imipramine and doxepin, and that the different incidence rates of arrhythmias and conduction disturbances associated with the clinical use of these drugs is probably not due to differences in their direct electrophysiologic effects on the ventricular specialized conduction system.

Electrocardiographic abnormalities and cardiac rhythm disturbances are frequently observed in patients who have ingested toxic doses of tricyclic antidepressant drugs. Although intraventricular conduction disturbances occur most frequently, atrioventricular (A-V) block and ventricular tachyarrhythmias are also common.[1,2] There is evidence that even in therapeutic doses these drugs have significant effects on the electrophysiologic properties of the heart. Reversible T wave abnormalities are commonly observed in patients taking such doses of these agents,[1–4] and sporadic cases of reversible right and left bundle branch block and of complete heart block have been reported.[3,5–7] In a prospective study Vohra et al.[8] showed that prolongation of the H-V interval in the His bundle electrogram occurred in 5 of 12 patients given therapeutic doses of nortriptyline. Kantor et al.[7] carefully studied a patient who manifested 2:1 heart block while receiving a therapeutic dose of imipramine (Tofranil®) and showed that the heart block was directly related to the plasma concentration of the drug and occurred below the A-V node in the His-Purkinje system. These investigators[9] subsequently reported that therapeutic doses of imipramine administered to elderly depressed patients regularly caused prolongation of the P-R, QRS and Q-T intervals. It has been noted[10] that patients receiving therapeutic doses of amitriptyline have a greater than expected incidence of sudden death. Bigger et al.[11] reported on two depressed patients in whom

therapeutic doses of imipramine significantly reduced the frequency of ventricular premature complexes.[11]

Among the various tricyclic antidepressant drugs, doxepin (Sinequan®) has been reported to cause no ventricular arrhythmias or conduction disturbances even when patients have ingested toxic doses or have heart disease.[8,12,13] With other tricyclic antidepressant drugs such as imipramine, such effects are rare in patients without heart disease when plasma levels of the drug are within the therapeutic range but they are virtually universal when plasma levels exceed 1,000 ng/ml.[13,14] It has been suggested that disturbances of intraventricular conduction, such as widening of the QRS complex, prolongation of the H-V interval and heart block, are more likely to occur at therapeutic blood levels of imipramine in patients who are elderly or who have preexisting heart disease, particularly disease of the ventricular specialized conduction system.[7,9]

This evidence indicates that among the tricyclic antidepressant drugs, some agents such as imipramine may cause cardiac arrhythmias, exert important effects on cardiac conduction (particularly in the His-Purkinje system) and manifest antiarrhythmic activity in patients with established ventricular arrhythmias, whereas other agents such as doxepin may not have these effects. This study was undertaken to determine if these differences could be explained on the basis of the direct electrophysiologic actions of these drugs on Purkinje fibers.

Methods

Experimental preparation: The hearts of healthy adult mongrel dogs weighing 10 to 20 kg were rapidly excised under general anesthesia with intravenous sodium pentobarbital (30 mg/kg body weight) and immediately dissected while immersed in cooled oxygenated modified Tyrode's solution containing (in mmol/liter): sodium chloride (137), sodium bicarbonate (12), dextrose (5.5), sodium phosphate (1.8), magnesium chloride (0.5), calcium chloride (2.8) and potassium chloride (4.0). False tendons were removed from the right and left ventricles, mounted in a tissue bath (volume 5 ml) and superfused at a flow rate of 20 ml/min with the Tyrode's solution equilibrated with 95 percent oxygen and 5 percent carbon dioxide at a temperature of 36 ± 1° C.

Stimulation and recording: All preparations were stimulated extracellularly at a cycle length of 800 ms with use of Teflon®-insulated bipolar silver electrodes located near one end of the preparation designated the proximal end. Basic drive stimuli were rectangular pulses 2 to 3 ms in duration and approximately twice diastolic threshold in amplitude. For experiments in which refractory periods were measured, premature impulses were delivered through the same electrode pair at selected intervals after the basic drive stimuli. The premature stimuli were rectangular pulses 2 to 3 ms in duration and greater than 5 times diastolic threshold. All stimuli were isolated from ground. Transmembrane potentials were recorded through glass microelectrodes filled with 3*M* potassium chloride and with tip resistances of 10 to 20 megohms. The microelectrodes were coupled by means of a silver-silver chloride electrode to a preamplifier with high input impedance (1.5×10^{12} ohms) and capacitance neutralization (constructed by S. Ross, Department of Pharmacology, Columbia University, New York, New York). The output of this preamplifier was displayed on a Tektronix model 5444 oscilloscope and photographed with a Grass model C4 oscilloscopic camera. The maximal rate of depolarization of action potentials was determined by electronic differentiation.[15]

Experimental protocols: Transmembrane resting and action potentials were initially recorded from all preparations after a minimum of 1 hour of perfusion with the modified Tyrode's solution described. Experiments were carried out only on preparations with Purkinje fibers exhibiting a resting membrane potential of −80 mV or more under these condi-

* $p < 0.05$; † $p < 0.01$ (statistical significance of the difference between control values and those obtained during drug exposure).
All values are expressed as mean ± standard error of the mean. The potassium concentration was 4.0 m*M* in all experiments. Amp = action potential amplitude; APD_{50} and APD_{100} = action potential duration at repolarization to 50 and 100 percent, respectively, of the amplitude of depolarization; RMP = resting membrane potential; $\dot{V}_{max}$ = maximal velocity of phase 0 depolarization.

tions. One of two different experimental protocols was then followed:

1. Normal tissues: Perfusion with Tyrode's solution was continued while two Purkinje fibers of the false tendon were impaled with microelectrodes, the proximal one lying within 1.5 mm of the stimulating electrode pair and the distal one lying 2 to 8 mm further toward the distal end of the preparation. The resting membrane potential, action potential amplitude, maximal upstroke velocity of phase 0 ($\dot{V}_{max}$) and action potential duration to repolarization to 50 percent and 100 percent of the amplitude (APD_{50} and APD_{100}, respectively) were recorded for each cell. The conduction time between the proximal and distal cells was determined by measuring the distance between mid point of the upstrokes of the two simultaneously displayed action potentials recorded at a rapid sweep speed. Then, with the transmembrane potentials of the two cells being recorded continuously on moving film, premature stimuli were introduced at progressively shorter coupling intervals after every eighth basic drive stimulus. The intervals between the responses to the basic drive and premature stimuli at the proximal site (P_1-P_2) and the distal site (D_1-D_2) were determined until excitation at the proximal site failed because of absolute refractoriness of those cells. The effective refractory period (ERP) was defined as the shortest P_1-P_2 interval at which conduction to the distal site was successful; the functional refractory period (FRP) was defined as the shortest D_1-D_2 interval achieved. After these recordings were made, imipramine or doxepin was added to the perfusate in a concentration of 50, 250, 500 or 1,000 ng/ml and observations were repeated after exposure to the drug for 40 minutes.

2. Depressed tissues: In these experiments depression of the Purkinje fiber action potentials was achieved by the addition of potassium chloride to the perfusing Tyrode's solution to give a final concentration of 10 mmol/liter. After 20 minutes of equilibration in this solution an experimental protocol identical to that outlined in (1) was followed except that the only concentration of imipramine and doxepin studied was 250 ng/ml.

Transmembrane resting and action potential data from an individual cell were not subjected to statistical analysis unless continuous impalement of the cell was maintained throughout the experimental protocol. If a microelectrode became dislodged in the course of an experiment it was replaced in the same or an adjacent cell by a small movement of the micromanipulator holding the electrode in the vertical plane only; the recordings obtained under such circumstances were used only for the determination of conduction times and refractory periods.

Analysis of data: Statistical analysis was performed using Student's *t* test for comparing means of nonindependent samples to assess the significance of any change caused by a given concentration of either drug in a given type of tissue preparation (normal or depressed). To compare the magnitude of change in an electrophysiologic variable caused in a given type of tissue preparation by the same concentration of the two different drugs, the *t* test for comparing means of independent samples was used.[16] In the latter case the change was first expressed as a percent of the control value for each experiment; the mean percent change was then determined for each of the two conditions being compared, and these two mean values were tested. A probability (p) value of <0.05 was considered significant.

Drugs: Pure drugs were obtained in powder form from their manufacturers: imipramine hydrochloride (Tofranil®, molecular weight 316.8) from Ciba-Geigy Canada Ltd., Dorval, Quebec, Canada and doxepin hydrochloride (Sinequan®, molecular weight 315.8) from Pfizer Canada Inc., Kirkland, Quebec, Canada. Fresh stock solutions were prepared each day by dissolving these drugs in double distilled water to give a final concentration of 100 mg/liter, and an appropriate amount of stock solution was then added to the Tyrode's reservoir to give the desired concentration. All doses of these drugs are expressed as concentrations of the salt.

Results

Effects on Normal Purkinje Fibers

Transmembrane resting and action potential characteristics (Table I): Neither imipramine nor doxepin exerted a measurable effect on the resting membrane potential of normal Purkinje fibers at concentrations of 50, 250, 500 or 1,000 ng/ml. However, marked effects were observed on the voltage time course of action potentials recorded from such fibers. The most sensitive variable was the action potential duration (APD), which was significantly shortened by both drugs in a dose-related manner. A significant effect (on APD_{50}) was apparent with doxepin at a concentration of 50 ng/ml; with imipramine, significant effects did not appear until a concentration of 250 ng/ml was tested. Shortening of APD_{50} was always more marked than that of APD_{100}, indicating that these drugs also caused a decrease in the slope of phase 3 of the action potential (Fig. 1).

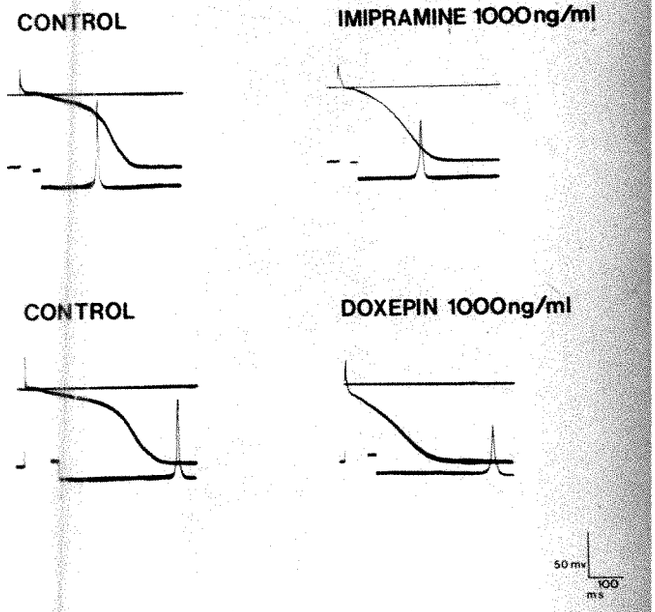

FIGURE 1. Effects of imipramine and doxepin on transmembrane resting and action potential characteristics of normal Purkinje fibers. In each panel the **upper tracing** is a zero reference potential, the **middle tracing** is a recording of the transmembrane potential, and the **lower tracing** is an electronic differentiation of the action potential upstroke preceded by a 200 V/s calibration square wave. The **left panels** were recorded under control conditions; the **right panels** were obtained after 40 minutes of exposure to imipramine, 1,000 ng/ml (**upper**) or doxepin, 1,000 ng/ml (**lower**). See text.

Both imipramine and doxepin also caused reductions in action potential amplitude and $\dot{V}_{max}$. With imipramine a significant effect on $\dot{V}_{max}$ was evident at a drug concentration of 250 ng/ml; with doxepin, this effect first achieved statistical significance at a concentration of 1000 ng/ml. A measurable effect on amplitude was apparent with both drugs only at a concentration of 1,000 ng/ml (Fig. 1).

Refractoriness and conduction (Table II): Both drugs reduced the effective and functional refractory periods of normal Purkinje fiber bundles (Fig. 2), an effect that was not surprising in view of the marked reduction of action potential duration. This effect was first apparent with each drug at a concentration of 250 ng/ml. The magnitude of the shortening of the functional refractory period was always very similar to that of the effective refractory period, indicating that the conduction velocity of early premature impulses was similar to that of the basic drive impulses. Conduction block of premature impulses between the proximal and distal recording electrodes was not observed. However, the conduction velocity of basic drive impulses was reduced by both imipramine and doxepin at concentrations of 1000 ng/ml, as indicated by the significant increases in conduction time that occurred (Fig. 2). The 47 percent increase that occurred with imipramine was not significantly different from the 25 percent increase with doxepin.

In fact, the effects of equivalent concentrations of imipramine and doxepin on the electrophysiologic properties of normal Purkinje fibers were generally quite similar. Although effects on certain variables such as APD_{50} and $\dot{V}_{max}$ achieved statistical significance when compared with control values at lower levels of doxepin than of imipramine (Table I), the mean percent changes produced by impramine were not significantly different from those caused by an equivalent concentration of doxepin for any measured variable at any drug concentration tested.

Effects on Depressed Purkinje Fibers (Tables III and IV):

Purkinje fibers that were depressed by increasing the concentration of potassium in the perfusate to 10 mmol/liter had low resting membrane potentials averaging about −63 mV. Action potentials recorded from such fibers had lower than normal values for $\dot{V}_{max}$, amplitude, APD_{50} and APD_{100} (Fig. 3). These were the expected effects of exposing Purkinje fibers to an increased extracellular potassium concentration.[17]

These depressed fibers were exposed only to a single concentration (250 ng/ml) of imipramine and doxepin. As in normal tissue, there was no detectable effect of either drug on resting membrane potential or action potential amplitude. Maximal upstroke velocity was reduced significantly only by imipramine; in normal tissues it had been reduced only by doxepin at this concentration. The APD_{50} and APD_{100} of the depressed fibers were further reduced by this concentration of imipramine and doxepin, as had been the case in normal fibers (Fig. 3). Despite these reductions, the effective and functional refractory periods of these depressed Purkinje fiber bundles were not shortened (Fig. 4). However, conduction time was increased significantly by both drugs at this concentration—a level that had not affected conduction time in normal preparations (Fig. 4).

Statistical comparison of the effects of imipramine with those of doxepin at this concentration on the electrophysiologic properties of depressed Purkinje fibers revealed no significant difference in any measured variables.

* $p < 0.05$; † $p < 0.01$ (statistical significance of the difference between control values and those obtained during drug exposure).
All values are expressed as mean ± standard error of the mean. The potassium concentration was 4.0 m*M* in all experiments. CT = conduction time from the proximal to the distal site; ERP = effective refractory period; FRP = functional refractory period.

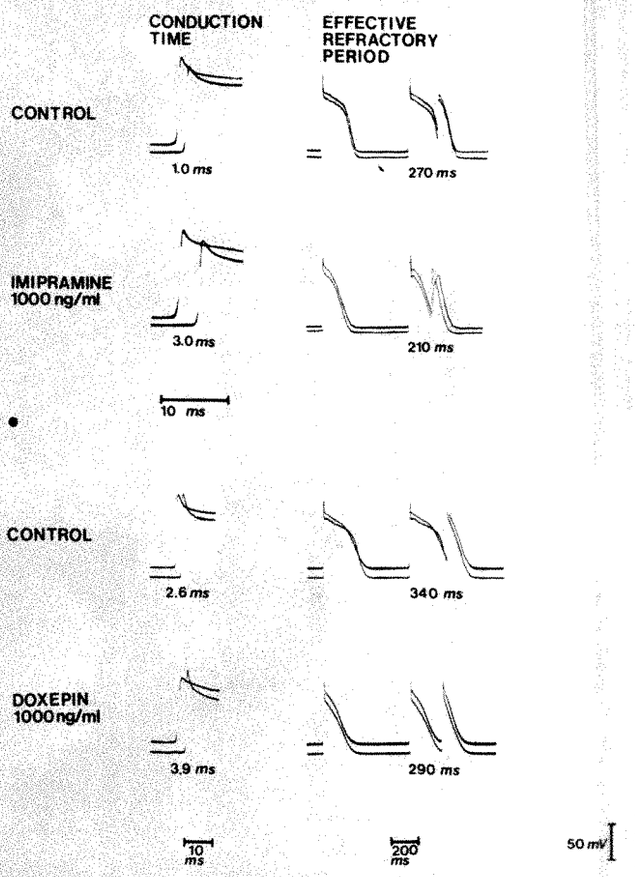

FIGURE 2. Effects of imipramine and doxepin on conduction and refractoriness in Purkinje fiber bundles perfused with Tyrode's solution having a potassium concentration of 4 mmol/liter. Each panel shows recordings made simultaneously from a proximal cell located within 2 mm of the stimulating electrodes and a distal one located approximately 4 mm farther along the bundle. The **left panels** illustrate the effects of these drugs on conduction time. Action potential upstrokes of the two cells are displayed at a rapid sweep speed. After 40 minutes of exposure to imipramine, 1,000 ng/ml, conduction time increased from 1.0 to 3.0 ms (**upper panels**). Exposure to an identical concentration of doxepin for the same period of time also resulted in an increase in conduction time, from 2.6 to 3.9 ms (**lower panels**). The **right panels** show the effects on the effective refractory period. Each panel shows the response of the two cells to the last two of a train of eight basic drive impulses at a cycle length of 800 ms, followed by the response to the earliest premature impulse that resulted in excitation at both the proximal and distal sites. Exposure to both imipramine and doxepin in concentrations of 1,000 ng/ml for 40 minutes resulted in marked shortening of the effective refractory period.

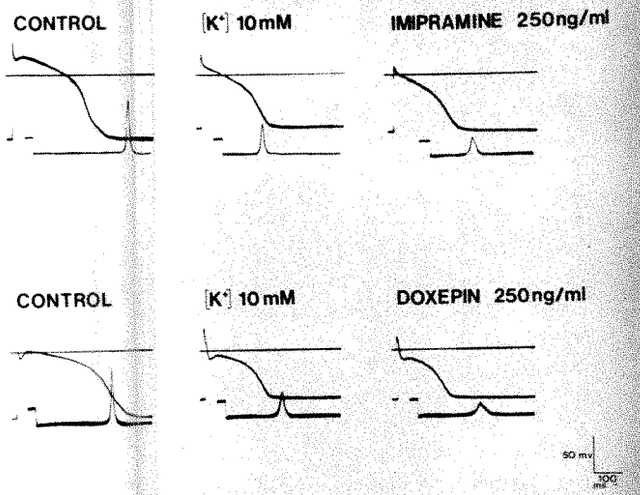

FIGURE 3. Effects of imipramine and doxepin on transmembrane resting and action potential characteristics of depressed Purkinje fibers. In each panel the **upper tracing** is a zero reference potential, the **middle tracing** is a recording of the transmembrane potential, and the **lower tracing** is an electronic differentiation of the action potential upstroke preceded by a 200 V/s calibration square wave. The **left panels** were recorded under control conditions with the fibers being perfused with normal Tyrode's solution. The **middle panels** were obtained after the fibers had been perfused for 20 minutes with Tyrode's solution containing a potassium concentration of 10 mmol/liter. The **right panels** were recorded 40 minutes after the addition of 250 ng/ml of imipramine (**upper**) or doxepin (**lower**) to the potassium-enriched Tyrode's solution. See text.

Discussion

An attempt was made to study concentrations of imipramine and doxepin that might occur in patients receiving these drugs. For imipramine the therapeutic range of plasma concentrations has been reported from as low as 95 to as high as 1,020 ng/ml[9,18]; for doxepin the range is from 19 to 250 ng/ml.[19–21] These figures represent total plasma concentrations not only of imipramine and doxepin but also of their active metabolites (desmethylimipramine and desmethyldoxepin, respectively). Imipramine has been estimated to be 75 to 95 percent protein-bound in vivo,[22] and hence the therapeutic range of the free drug would be correspondingly reduced. The extent of protein binding of

doxepin has not been reported. With these qualifications, and others to be discussed, it may be surmised that in our study the effects of imipramine or doxepin in a concentration of 250 ng/ml probably correspond with, or slightly exceed, the effects of a therapeutic plasma level in patients.

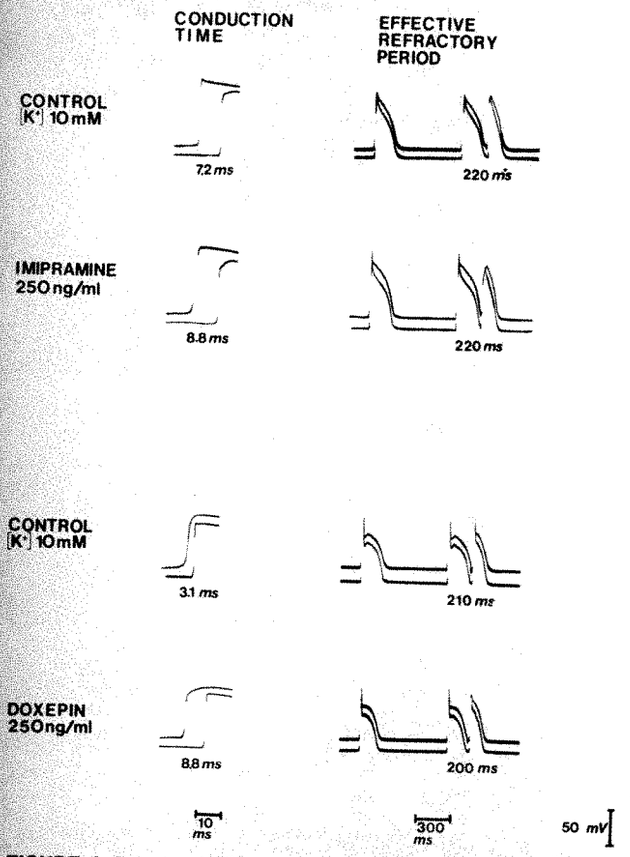

FIGURE 4. Effects of 250 ng/ml of imipramine (**upper panels**) and doxepin (**lower panels**) on conduction and refractoriness in depressed Purkinje fibers. Each panel shows simultaneous recordings from a proximal cell located within 2 mm of the stimulating electrodes and a distal one approximately 4 mm farther along the bundle. The potassium concentration in the perfusate was 10 mmol/liter in all recordings. In the **left panels** the action potential upstrokes are displayed at a rapid speed. Each **right panel** shows the response of the two cells to the last two of a train of eight basic drive impulses at a cycle length of 800 ms, followed by the response to the earliest premature impulse that resulted in excitation at both sites. The interval between these two impulses defines the effective refractory period. See text.

Comparative drug effects on normal Purkinje fibers: This study revealed that both drugs had similar effects on transmembrane resting and action potentials of normal Purkinje fibers. Neither imipramine nor doxepin affected resting membrane potential but each drug caused dose-related reductions of both action potential amplitude and $\dot{V}_{max}$, indicating a depressant effect on the rapid inward sodium current. Both drugs also shortened the action potential duration, an effect that cannot be explained on the basis of altered kinetics of the rapid inward sodium current and that implies either a reduction in slow inward current or an increase in outward current. The reduction of conduction velocity in normal Purkinje fibers observed at high drug concentrations could be due to the reductions of action potential amplitude and $\dot{V}_{max}$ because these are major determinants of conduction velocity,[23] whereas the drug-induced shortening of the effective and functional refractory periods could be explained by the reduction of action potential duration, because reactivation of the rapid inward sodium current is a highly voltage-dependent process.[24,25]

Comparative drug effects on depressed Purkinje fibers: The resting membrane potential was reduced to approximately −63 mV in some experiments by elevating the extracellular potassium concentration. This represented an attempt to alter the electrophysiologic properties of Purkinje fibers to simulate certain pathologic conditions, because reduction of the resting membrane potential is commonly observed in the cells of diseased hearts.[26–29] Such cells uniformly exhibit action potentials with reduced amplitudes and $\dot{V}_{max}$. Under the conditions used to depress Purkinje fibers in our study (potassium concentration 10 m*M*) the reduction in action potential amplitude and $\dot{V}_{max}$ was due to partial inactivation of the rapid inward sodium current.[24,25,30] The study did not examine the effects of imipramine and doxepin on severely depressed fibers exhibiting action potentials due entirely to the slow inward current.

On moderately depressed Purkinje fibers the effects of imipramine and doxepin were examined only at a concentration of 250 ng/ml in an effort to determine whether such fibers were more sensitive than normal fibers to therapeutic drug concentrations. With respect to transmembrane resting and action potential characteristics no such enhanced susceptibility was found. The effective and functional refractory periods of de-

pressed preparations, which were already considerably shorter than those of normal preparations (compare Table III with Table I), were unaffected by 250 ng/ml of imipramine and doxepin, that is, they were less influenced than those of normal tissues by this concentration of the drugs.

Comparative drug effects on conduction velocity: Perhaps the most important finding in this study was the effect of imipramine and doxepin on conduction velocity. Although both drugs slowed conduction in normal fibers only at a concentration of 1,000 ng/ml, a similar effect was apparent in depressed fibers at 250 ng/ml. In normal tissues this effect would be explained by reductions in action potential amplitude and $\dot{V}_{max}$ but in depressed tissues there was no clear relation between these variables and conduction velocity: $\dot{V}_{max}$ of depressed fibers was significantly reduced by 250 ng/ml of imipramine but not by doxepin, and action potential amplitude was not influenced by either drug. These findings imply that the drugs also affected one or more of the other determinants of conduction velocity such as membrane resistance, membrane capacitance or threshold for excitation.[23]

In previous studies[31,32] of the actions of imipramine on normal Purkinje fibers, it was found, as in this study, that the drug did not affect resting membrane potential but reduced $\dot{V}_{max}$ and action potential duration. In addition, Weld et al.[31] noted that imipramine increased the voltage threshold for excitation but did not affect the slope of spontaneous phase 4 depolarization. As in this study, Rawling and Fozzard[32] noted that imipramine caused slowing of conduction at a concentration of 1,000 ng/ml. They also found that it reduced membrane responsiveness, reduced the lowest transmembrane potential from which the cell could be stimulated and delayed the recovery of the rapid inward sodium current. Neither the effects of imipramine on depressed fibers nor the effects of doxepin on either normal or depressed fibers have previously been reported.

Clinical correlations: With respect to imipramine, the results of this study correlate with certain clinical observations. Slowing of conduction in normal Purkinje fibers at a high drug concentration (1,000 ng/ml) could explain the occurrence of intraventricular conduction disturbances and heart block in patients without heart disease who have ingested toxic doses of the drug. Ventricular tachyarrhythmias in such patients could be due to unidirectional block and reentry in the ventricular specialized conduction system as a result of drug-induced depression of conduction.[33] The observation in this study that depressed fibers are more sensitive than normal fibers to imipramine-induced slowing of conduction may explain the development of intraventricular conduction disturbances even with therapeutic doses of the drug in patients with heart disease. Finally, therapeutic doses of imipramine have been noted to decrease the frequency of ventricular premature complexes. Such complexes might be due to slow conduction, unidirectional block and reentry in the ventricular specialized conduction system.[33] Imipramine, by further depressing conduction in such regions, might abolish the unidirectional block and thereby abolish the premature complexes.[34]

In contrast, doxepin has not been reported to cause conduction disturbances or arrhythmias. This study suggests that this difference is probably not due to intrinsic differences between the direct electrophysiologic effects of doxepin and imipramine on the ventricular specialized conduction system but may be due to the generally lower plasma drug levels in patients receiving doxepin than in those receiving imipramine.

Other factors must also be considered. The assumption that the electrophysiologic effects of imipramine and doxepin on human and canine Purkinje fibers are similar in vivo and in vitro may or may not be valid. The metabolism of tricyclic antidepressant drugs in vivo produces metabolites that have antidepressant activity[35] and that may affect cardiac electrophysiologic properties; such effects were not assessed in this study. Finally, imipramine and doxepin produce adrenergic and anticholinergic effects[2,35] that probably influence the electrophysiologic properties of the heart. The present study did not examine the possible interactions of such indirect effects of these drugs with their direct electrophysiologic effects. Thus, although this study has shown that the direct electrophysiologic actions of imipramine and doxepin on isolated canine Purkinje fibers are similar, and that moderately depressed fibers are more sensitive than normal fibers to certain of these effects, further investigation is required before the clinical significance of these observations can be ascertained.

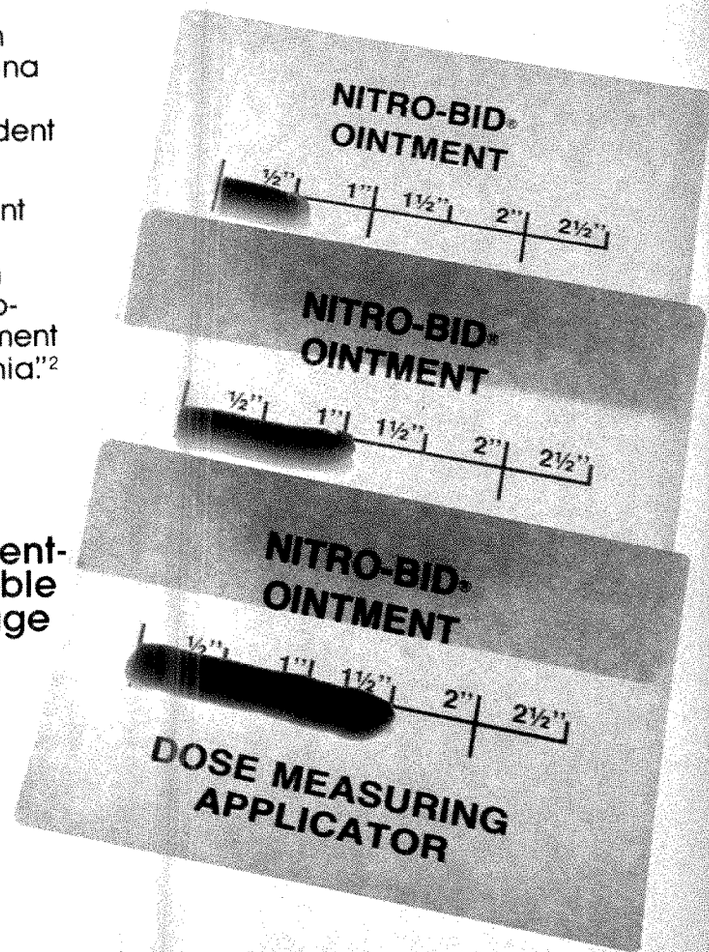
In angina pectoris...

NITRO-BID®
(2% nitroglycerin)
Transdermal Ointment



For prolonged prophylactic action

"Cutaneous administration of Nitroglycerin ointment (NITRO-BID®) in patients with angina pectoris exhibits prolonged action with evidence of pharmacological activity evident up to eight hours after application."[1]

"...data indicate that nitroglycerin ointment (NITRO-BID®) exerts profound reduction of peripheral arteriolar and venous tone with resultant alterations in left ventricular hemodynamic variables which afford enhancement of exercise tolerance and reduced ischemia."[2]

Patient-titratable dosage

Brief Summary:

Description: Nitroglycerin 2% (glyceryl trinitrate) and lactose in a special absorptive lanolin and white petrolatum base.

Action: Nitroglycerin is continuously absorbed through the skin into the circulation, thus exerting prolonged vasodilator effects.

Indications: For the prevention and treatment of angina pectoris due to coronary artery disease.

Contraindications: In patients known to be intolerant of the organic nitrate drugs.

Warnings: In acute myocardial infarction or congestive heart failure, nitroglycerin ointment should be used under careful clinical and/or hemodynamic monitoring.

Precautions: Symptoms of hypotension, particularly when suddenly arising from the recumbent position, are signs of overdosage. When they occur, the dosage should be reduced.

Adverse Reactions: Transient headaches are the most common side effect, especially at higher dosages. Headaches should be treated with mild analgesics, and nitroglycerin ointment continued. Only with untreatable headaches should the dosage be reduced. Although uncommon, hypotension, an increase in heart rate, faintness, flushing, dizziness, and nausea may occur. These all are attributable to the pharmacologic effects of nitroglycerin on the cardiovascular system, but are symptoms of overdosage. When they occur and persist, the dosage should be reduced.

Dosage: Usual dose is 2 inches (50mm), as squeezed from the tube, every eight hours. Some patients may need 4 to 5 inches (100 to 125 mm) and/or application every four hours. Optimal dosage should be based upon clinical response, side effects, and effects of therapy upon blood pressure. Consult full product disclosure before prescribing.

Pharmacokinetics

Ativan (lorazepam) is eliminated more rapidly than other benzodiazepines; generates no clinically active metabolites. The half-life of free lorazepam is about 12 hours; steady-state blood levels are attained in 2-3 days. (Comparable data for diazepam: 20-50 hours and at least 7-10 days.) Ativan shows no evidence of accumulation, even when given in high doses for as long as 6 months. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Anxiety neuroses

In many nationwide studies involving thousands of patients with anxiety neuroses, Ativan (lorazepam) consistently provided significant relief of anxiety, tension, agitation and irritability as measured by standard Hamilton, Global (physician rated) and 35-Item (patient self-rated) scales.

They're all about the same, aren't they? Until recently, that seemed to sum up the prevalent attitude about the benzodiazepines. After all, they all work similarly and all are effective anxiolytics. With seven of these compounds now available, however, differences have begun to emerge. Foremost among them: different metabolic pathways, which distinguish the relatively short-acting Ativan (lorazepam) from long-acting diazepam, clorazepate and chlordiazepoxide. At the same time, your choice can be made with confidence in the clinical record of Ativan, which confirms its value in anxiety neuroses and in significant anxiety associated with functional or organic disorders, as well as in older patients.

Consider the record of Ativan:

Anxiety in cardiovascular disorders

Ativan (lorazepam) has been specifically evaluated and found effective in seven common protocol, double-blind studies involving 423 patients (211 on Ativan) whose anxiety was related to organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in gastrointestinal disorders

So far, nine common protocol, double-blind studies of Ativan have focused on anxious patients with functional or organic gastrointestinal complaints (457 patients, 234 on Ativan). Ativan was clearly effective in reducing the anxiety of these patients. The gastrointestinal component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in the aging patient

Because its simple metabolism is not readily impaired with advancing age, and accumulation is not likely to present a problem, Ativan is a good choice for older patients. Those who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

Ativan® (lorazepam) for Anxiety

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Intermedics Pulse Generators

INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacemaking are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting with intractable, recurrent, congestive heart failure; cerebral or renal insufficiency; or recurrent, drug-resistant tachyarrhythmias who have been shown to benefit from temporary cardiac pacing are considered candidates for permanent cardiac pacemaking.

The indications for permanent pacing in the presence of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, mechanism of the arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias which impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. However, body rejection phenomena such as local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

CAUTION: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

NOTE: The CyberLith and the CyberLith Programmer are currently undergoing clinical evaluation.

Intermedics Inc.
Our business is life.™

The CyberLith programming system.

Reliable, safe, convenient. And available.

CyberLith... the most sophisticated programming system ever.

Reliable

The CyberLith all electronic programming system assures reliability by eliminating phantom or cross-programming. The use of accurate crystal oscillators ensures precision transmission of programming information.

Safe

The CyberLith programming safety features help avoid unnecessary cardiac rhythm disturbances. Further, it is not necessary to place the pulse generator in the asynchronous mode during the programming session. The safety features also allow automatic error identification, preventing transmission of incompatible programming commands.

Convenient

The CyberLith programming system is fast — all five parameters are programmed within 40 milliseconds.

Available

CyberLith pacing systems are available now! Pulse generators, programmers, leads, telemetry equipment, and patient transmitters and receivers.

As the pioneers of multi-parameter programmable pacing technology, Intermedics has maintained its role as the manufacturer of the most advanced systems. Our commitment is to keep in pace with your desire for excellence in pacing therapy.

The CyberLith system is today's state-of-the-art. Get to know it. For more detailed information call or write the Intermedics marketing department, or contact your local Intermedics representative.

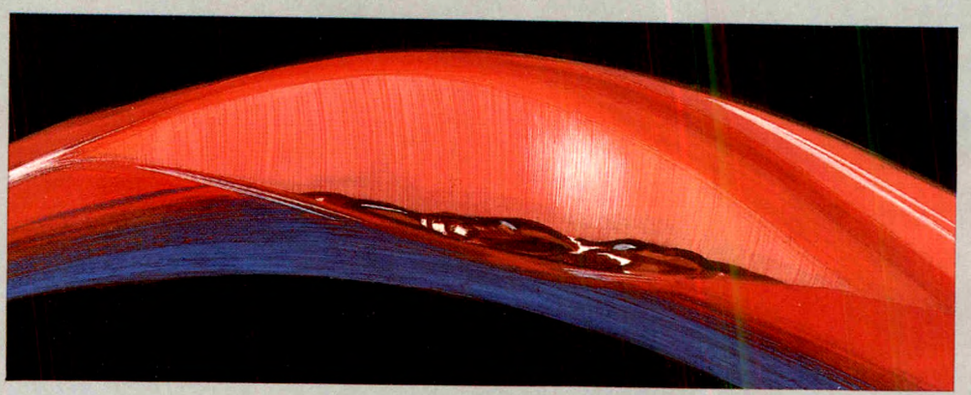
A life-threatening

pulmonary embolus

is being dissolved by



Artist's conception, based on changes in pulmonary angiography following Breokinase infusion.[1]

NEW BREOKINASE®
(urokinase)

NEW BREOKINASE®
(urokinase)

for injection

Rapid and effective dissolution of pulmonary emboli.

- Proven by controlled clinical studies.[1]
- More rapid and effective than heparin alone during the first 24 hours after start of therapy.[2]

1. Sasahara AA, Hyers TM, Cole CM, et al: The urokinase pulmonary embolism trial. *Circulation* (Suppl II) 47:1-108, 1973.
2. Fratantoni JC, Ness P, Simon TL: Thrombolytic therapy: Current status. *N Eng J Med* 293:1073-1078, 1975.

Please see prescribing information on last page of this advertisement. It is important to pay close attention to WARNINGS and CONTRAINDICATIONS sections to minimize the risk of bleeding.

New Breokinase® is highly purified human protein.

- Lower incidence of fever.[3,4]*
- Can be used effectively in patients with recent streptococcal infections or high titers of streptococcal antibodies.
- Less risk of allergic reactions than streptokinase.†

Now urokinase therapy at lower cost

- Offers substantial savings to both hospital and patient.
- Convenient. Ask your Breon representative for a list of depots. There is one near you.

*Febrile episodes occurred in about 2-3% of urokinase-treated patients. A causal relationship to urokinase has not been established.

†In vitro and intradermal tests gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions occurring cannot be excluded. There have been rare reports of relatively mild allergic reactions such as bronchospasm and rash.

3. Sasahara AA, Bell WR, Simon TL, Stengle JM, Sherry S: The phase II urokinase-streptokinase pulmonary embolism trial. *Thrombos Diathes Haemorrh (Stuttg)* 33:464-476, 1975.

4. Urokinase pulmonary embolism trial study group: Urokinase-streptokinase embolism trial. *JAMA* 229:1606-1613, 1974.

Doctor: Before prescribing or administering Breokinase® (urokinase for injection) please read the following product information.

BREOKINASE®

(urokinase) for injection

Breokinase (urokinase for injection) should be used only by physicians with adequate experience in the management of thrombotic disease in hospitals where necessary clinical and laboratory monitoring can be performed (see Warnings, Precautions and Dosage and Administration).

The physician should carefully assess the overall clinical status and history of the patient before beginning urokinase treatment. Urokinase produces more profound changes in hemostasis and a greater frequency of bleeding than heparin or oral coumarin anticoagulant therapy. Bleeding when it occurs is more severe and more difficult to manage. Such factors as patient's age, physical condition, and underlying bleeding tendency (as described under Warnings and Precautions) should be taken into consideration when the potential risk of serious hemorrhage is weighed against the potential benefits of urokinase treatment.

Indications

Breokinase is indicated for the thrombolytic treatment of:

—acute massive pulmonary embolism, defined as obstruction or significant filling defects involving two or more lobar pulmonary arteries or an equivalent amount of emboli in other vessels, as seen on pulmonary arteriography;

—pulmonary embolism accompanied by unstable hemodynamics, i.e., inability to maintain blood pressure without supportive measures.

The diagnosis of pulmonary embolism should be confirmed by objective means, preferably pulmonary arteriography.

Urokinase treatment should be started as soon as possible after diagnosis of pulmonary embolism, but no later than five days after onset. Under these circumstances, angiographic and hemodynamic measurements and perfusion lung scans demonstrate a more rapid improvement during the first 24 hours after initiation of therapy than with heparin therapy. However, it has not been established that urokinase treatment decreases morbidity or mortality compared to heparin therapy alone.

Contraindications

Thrombolytic therapy increases the risk of bleeding. The risk of hemorrhage in the conditions listed below should be weighed carefully against the anticipated benefits of urokinase therapy in each patient. The benefits and risks associated with urokinase therapy should be compared to the benefits and risks associated with other forms of treatment.

1. Surgical procedures within preceding ten days (including liver or kidney biopsy, lumbar puncture, thoracenteals, paracentesis, extensive or multiple cutdowns).
2. Intraarterial diagnostic procedure within ten days.
3. Ulcerative wound.
4. Recent trauma with possibility of internal injuries.
5. Visceral or intracranial malignancy.
6. Pregnancy and the first ten days post-partum.
7. Actively bleeding lesion of the gastrointestinal or genitourinary tract, or a condition with significant potential for bleeding (including ulcerative colitis, diverticulitis).
8. Severe hypertension.
9. Acute or chronic hepatic or renal insufficiency.
0. Uncontrolled hypocoagulable state (including coagulation factor deficiency, thrombocytopenia, spontaneous fibrinolysis, any purpuric or hemorrhagic disorder).
1. Chronic pulmonary disease with cavitation, e.g., tuberculosis.
2. Subacute bacterial endocarditis or rheumatic valvular disease.
3. Recent cerebral embolism, thrombosis or hemorrhage (within at least two months) to avoid risk of bleeding into infarcted cerebral tissue.
4. Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to locate or control.

Warnings

Bleeding: Activation of the fibrinolytic system with urokinase causes a more profound change in the hemostatic status of the patient than does anticoagulant therapy with heparin or coumarin agents. The objective of urokinase therapy is the production of sufficient amounts of plasmin to lyse intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example at sites of needle punctures, will also undergo lysis, and bleeding from such sites may occur. The possibility of bruising or hematoma formation, especially with intramuscular injections, is substantial during thrombolytic therapy. Unnecessary clinical or diagnostic procedures should be avoided. It is important that close attention be paid to this section and the Contraindications section in order to minimize the risk of bleeding.

Intramuscular injections should be avoided during urokinase therapy, as with heparin therapy, because of the high risk of hematoma formation. Bleeding may occur at sites of recent invasive procedures. Therefore, arterial punctures must be avoided before as well as during treatment with urokinase. If arterial puncture is *absolutely* necessary, the radial or brachial artery should be used and the femoral artery must be avoided. Arterial puncture should be performed with great care by an experienced physician and pressure should be applied for at least 15 minutes. This should be followed by the application of a pressure dressing, and the puncture site should be checked frequently for evidence of bleeding.

Venipunctures should also be performed as carefully and infrequently as possible. If bleeding from an invasive site occurs during urokinase infusion, but is not severe, treatment may be continued with close clinical observation. Local pressure and other measures should be initiated immediately.

Spontaneous internal bleeding that is not accessible for the application of pressure may also occur. The risk of spontaneous bleeding is greater in patients with pre-existing hemostatic abnormalities, including patients whose histories are suggestive of prior bleeding problems whether or not there are demonstrable abnormalities in platelet count, prothrombin time, partial thromboplastin time, or bleeding time. The relative risks and benefits of urokinase treatment must be carefully assessed in such patients before initiating treatment.

Plasmin degrades fibrinogen, Factor V, Factor VIII, and other proteins in addition to fibrin. The products of plasmin degradation of fibrinogen and fibrin (FDP/fdp) possess an anticoagulant effect which may make bleeding difficult to control.

If serious spontaneous bleeding occurs, the infusion of urokinase should be terminated immediately, and treatment instituted as described under Adverse Reactions.

Risk of Cerebral Embolism

Urokinase treatment of patients with atrial fibrillation or other conditions which predispose to cerebral embolism may be hazardous because of the risk of bleeding into the infarcted cerebral area.

Use of Anticoagulants

Concurrent use of anticoagulants with urokinase may be hazardous and is not recommended. Before beginning urokinase infusion in patients being treated with heparin, the effects of heparin should be allowed to decrease, as evidenced by a thrombin time of less than twice normal or an activated partial thromboplastin time (APTT) of less than one and one-half times normal. Similarly, heparin should be withheld for four hours following urokinase therapy unless the prothrombin time is in the normal range.

Rethrombosis has been observed after completion of urokinase treatment. In order to minimize this risk, administration of intravenous heparin followed by oral anticoagulant therapy is considered a necessary adjunct following urokinase therapy (see Dosage and Administration).

Use in Pregnancy

See Contraindications.

Use in Children

Safety and effectiveness of urokinase therapy in children have not been established; therefore, treatment of such patients is not recommended.

Precautions

Drug Interactions

Drugs that may alter platelet function, e.g., aspirin, indomethacin, and phenylbutazone, should be avoided during urokinase treatment. The interaction of BREOKINASE with other drugs has not been studied.

Laboratory Monitoring

In patients who have received heparin, the thrombin time or APTT should be measured prior to starting urokinase. (See Warnings.) Similarly, the prothrombin time should be monitored during and following urokinase therapy prior to instituting heparin. (See Dosage and Administration.) During urokinase administration, the levels of fibrinogen, plasminogen, Factor V, and Factor VIII are usually substantially decreased, and the level of fibrin and fibrinogen degradation products (FDP/fdp) is increased. Reduced fibrinogen and increased FDP/fdp result in a prolongation of the prothrombin time. Changes in these tests serve as confirmation of the existence of a lytic state. There are no data to indicate that alteration of dosage is required on the basis of these tests, although as a general rule the prothrombin time should not be allowed to increase above 30 seconds.

Urokinase infusion should be terminated immediately if serious bleeding occurs.

Adverse Reactions

Careful observance of the contraindications, warnings, and precautions to the use of urokinase is essential to minimize the incidence and severity of adverse effects.

Bleeding

Incidence

In controlled clinical trials of streptokinase and urokinase, severe bleeding (requiring a transfusion of greater than two units of blood) was seen in 4% of streptokinase patients and 6% of patients receiving urokinase. Several fatalities due to cerebral hemorrhage have occurred during urokinase therapy.

Spontaneous bleeding of a less severe degree has been observed during urokinase treatment at about twice the frequency as that occurring during heparin therapy. Oozing of blood from sites of skin puncture is frequent; therefore, all invasive procedures, especially arterial punctures and intramuscular injections, should be avoided and intravenous punctures kept to a minimum before and during treatment with urokinase.

A moderate decrease in hematocrit not accompanied by clinically detectable bleeding was observed in about 20% of patients treated with urokinase.

Management of Severe Bleeding

Urokinase therapy must be discontinued if serious bleeding occurs. Packed red cells are indicated for large blood loss. Plasma volume expanders (other than Dextran) may be used to replace blood volume deficit. Whole blood may also be used if it alone is available. The use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for urokinase has not been documented, but its use may be considered if the hemorrhage is unresponsive to blood replacement (see Warnings).

Allergic Reactions:

Urokinase is a protein of human origin, and *in vitro* as well as intradermal tests in humans gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions (including anaphylaxis) occurring during its use cannot be excluded. There have been rare reports of relatively mild allergic reactions, e.g., bronchospasm and skin rash.

Fever:

Febrile episodes occurred in about 2-3% of urokinase-treated patients. A causal relationship to urokinase has not been established. Symptomatic treatment with acetaminophen rather that aspirin is usually sufficient.

Dosage and Administration

Preparation

Reconstitute each vial of Breokinase by aseptically adding 8.0 ml of Sterile Water for Injection, U.S.P. (It is important that *only* Sterile Water for Injection, U.S.P., *without* preservatives, be used. Bacteriostatic Water for Injection or other diluents should not be used.) Swirl gently to avoid foaming. **Do Not Shake.** Because Breokinase contains no preservatives, it should not be reconstituted until immediately before using. Any unused portion of the reconstituted material should be discarded.

Each ml of reconstituted Breokinase contains 31,250 C.T.A. Units of urokinase activity.

Dosing

Breokinase is intended for Intravenous Infusion Only

Urokinase treatment should be begun as soon as possible after the occurrence of pulmonary embolism, and no later than five days after onset. A priming or loading dose of 2000 C.T.A. Units/lb (4400 C.T.A. Units/kg) of reconstituted Breokinase is given over a period of ten minutes. This is followed by a continuous infusion of 2000 C.T.A. Units/lb/hr (4400 C.T.A. Units/kg/hr) for 12 hours.

A constant infusion pump independent of all other intravenous systems should be used. Do not expose reconstituted solution to excessive heat, such as high intensity lights, during administration.

Anticoagulation Following Breokinase Treatment

At the end of Breokinase infusion, treatment with heparin by continuous intravenous infusion followed by oral anticoagulant therapy is recommended to minimize rethrombosis. Heparin treatment should begin 4 hours after Breokinase infusion, or sooner if the prothrombin time has returned to normal. See manufacturer's prescribing information for proper use of heparin.

How Supplied

Breokinase is supplied as a sterile lyophilized preparation. Each vial contains 250,000 C.T.A. Units of urokinase activity and approximately 0.9 millimols sodium phosphates. The vials should be stored at or below 4° C.

Transcutaneous Method of Measuring Doppler Cardiac Output—I

Comparison of Transcutaneous and Juxta-aortic Doppler Velocity Signals With Catheter and Cuff Electromagnetic Flowmeter Measurements in Closed and Open Chest Dogs

JOHN R. DARSEE, MD*
J. RONALD MIKOLICH, MD
PAUL F. WALTER, MD
ROBERT C. SCHLANT, MD, FACC

Atlanta, Georgia

Cardiac output values obtained by thermodilution technique in 20 closed and open chest dogs were compared with values obtained by multiplying the integral of Doppler systolic velocity signals of aortic flow in 1 minute by the cross-sectional area of the aortic root. Doppler velocity signals were measured either from immediately outside the proximal aortic wall or from outside the chest wall during (1) the baseline state, (2) after 500 ml of hemorrhage, and (3) after reinfusion, (4) after administration of propranolol, and (5) during infusion of dopamine. In addition, Doppler "stroke volume" waveforms were compared with those obtained by electromagnetic flowmeter. Results showed a close similarity between Doppler signals and electromagnetic waveforms, and a close correlation between Doppler and thermodilution values for cardiac output except at heart rates exceeding 160 beats/min. The studies showed the transcutaneous Doppler method of measuring cardiac output to be an accurate and reliable technique with application to clinical heart disease.

The noninvasive measurement of cardiac output has been of interest to clinicians for years. Echocardiography is a useful technique but is not accurate in patients with large ventricular volumes or dyskinetic myocardial segments. Furthermore, an adequate left ventricular view is not obtainable in many patients. Radionuclide gated blood pool scanning appears to be an excellent noninvasive method for measuring cardiac output, ejection fraction and other indexes of ventricular performance. However, the expense of equipment and the safety procedures necessary for the preparation of isotopes may limit its availability in some hospitals. Aortic systolic velocity measurements have been obtained using a transcutaneous continuous wave Doppler velocity meter in human beings[1] and in laboratory animals.[2] Changes in the analog integral of the systolic velocity curve have shown a close correlation with changes in stroke volume extrapolated from cardiac output values obtained by thermodilution. To determine whether the velocity signals obtained with a remotely positioned transcutaneous Doppler probe were similar to those obtained with a Doppler probe positioned 1 cm from the aorta and with those from an electromagnetic flow probe, we performed the following study in closed and open chest dogs under controlled conditions as a prelude to studies in human beings.

Methods

Experimental protocol: Twenty mongrel dogs of either sex weighing from 18 to 30 kg were anesthetized with thiamylal sodium (30 mg/kg body weight) and morphine sulfate (3 mg/kg) subcutaneously, intubated and mechanically ventilated. A heparin-filled catheter was placed in the left ventricle retrograde from the right femoral artery. An electromagnetic catheter flow probe (Carolina Medical Electronics model EP 1008P) was positioned in the proximal aorta and energized with an electromagnetic flowmeter (Carolina Medical Electronics). A balloon-tipped flotation catheter (Edwards Laboratories) was positioned in the pulmonary artery and thermodilution cardiac output was measured with an Edwards cardiac output computer (model 9510-A).

From the Department of Medicine (Cardiology), Emory University School of Medicine, Atlanta, Georgia. FIGURE 1. Representative tracing showing simultaneous electromagnetic flow and Doppler velocity signals. The Doppler probe is outside the thoracic cage. The 75 cm/s calibration applies to the peak velocity. The 30 cm^3 refers to the actual stroke volume of the electromagnetic flow signal depicted. Time lines are 0.04 second apart. AP = arterial pressure; ECG = electrocardiogram; LVP = left ventricular pressure.

Closed chest measurements: The transducer (diameter 16.0 mm) of a 2.2 megahertz bidirectional continuous wave Doppler velocity meter (Bach-Simpson Limited, model BVM20) was positioned superior to the right clavicle approximately 2 cm lateral to the suprasternal notch. The probe direction resulting in the maximal peak velocity from the proximal aorta was fixed with a C clamp attached to an overhead bar. All signals were recorded on an Electronics for Medicine eight channel recorder. Signals from the Doppler velocity meter and the electromagnetic catheter flow probe were recorded simultaneously while thermodilution cardiac output values were obtained. Measurements were made (1) in the baseline state, (2) after 500 ml of blood was removed through an arterial catheter, (3) after reinfusion of the blood in 100 ml increments, (4) during an infusion of dopamine in doses of 4, 10 and 16 μg/kg per min, and (5) after intravenous administration of propranolol (0.5 mg/kg).

Open chest measurements: After all closed chest measurements were completed, the chest was opened and an electromagnetic cuff flow probe (Carolina Medical Electronics, model EMP-445 or EMP-450) was placed snugly around the proximal aorta. The transducer (diameter 11 mm) of an 8 megahertz continuous wave Doppler ultrasonic velocity meter (Sonicaid Limited, model BV 381) was positioned just above the cuff flow probe and separated from the aortic wall by a thin membranous bag of ultrasonic gel (approximately 5 ml capacity) to dampen artifacts produced by aortic wall motion. The direction of the internal Doppler probe was varied to obtain the maximal peak velocity and was consistently parallel to the caudocephalad direction of the proximal aorta. The external transcutaneous Doppler probe was repositioned as previously described; however, the main pulmonary artery and brachiocephalic vessels were each temporarily occluded by clamping to determine whether aortic flow velocity alone was being measured. The two Doppler signals, the electromagnetic flow probe signal and thermodilution cardiac output values were recorded under the various hemodynamic conditions produced with the chest closed.

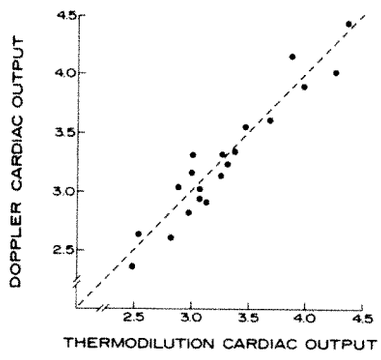

FIGURE 2. Linear regression plot of Doppler against thermodilution cardiac output values in liters/min for each of the 20 dogs during the baseline state. The **dashed line** is the line of identity. The correlation coefficient for the regression line is 0.96, slope = 0.98, the y intercept = 0.12, and the standard error of the estimate is 0.06 liters/min.

Standardization of signals: *Doppler signals:* Both Doppler instruments are provided with a square wave stimulus with a magnitude of either 50 or 100 cm/s for standardizing the measured instantaneous and peak velocities. Zero flow was obtained in the open chest dogs by temporary occlusion of the aorta, and electronically in closed chest dogs.

Electromagnetic flowmeter signals: Both the electromagnetic catheter flow probe and the cuff flow probe signals were calibrated by dividing the values for cardiac output obtained by thermodilution by the pulse rate. The cuff flow probe was also calibrated by cutting out the segment of aorta containing the probe and measuring mean flow of heparinized blood produced by a source with a known flow rate.

Analog integrator: The area beneath each Doppler velocity signal was automatically determined using a two channel in-line analog integrator (Carolina Medical Electronics, model 312).

Doppler signal processing: The continuous wave Doppler-shift frequencies were processed with a zero-crossing detector. This detector converts the frequency information to an analog voltage output that represents the root-mean-square of velocity of blood in the vessel in the region of the insonating Doppler beam.

Calculation of stroke volume from Doppler signals: The circumference of the aorta at the attachment site of the cuff flow probe was measured and the cross-sectional area (A) was calculated from the circumference (C) using the formula $A = C^2/4\pi$. A cardiac output value was calculated by multiplying the aortic cross-sectional area by the sum of the velocity integrals in systole for a 1 minute period (area × length [or distance of flow] = volume). Stroke volume was calculated by multiplying the aortic cross-sectional area by the height of an individual velocity integral.

Statistical methods: The following comparisons of values for stroke volume were made using linear regression[3]: (1) transcutaneous Doppler with catheter flow probe (closed chest dogs); (2) juxta-aortic Doppler with cuff flow probe; (3) transcutaneous with juxta-aortic Doppler; and (4) transcutaneous Doppler with cuff flow probe (open chest dogs). A correlation coefficient, slope, y intercept, and standard error of the estimate were calculated using values obtained in each dog separately because a regression analysis using values obtained in all dogs under different conditions is not statistically valid. We did, however, construct a regression line for values obtained in all dogs during the baseline state only.

Results

Experiments in Closed Chest Dogs

Comparison of waveforms: The Doppler waveform remained positive throughout systole, peaked between one third and one half of its total duration and usually had a brief negative dip in early diastole followed by a small positive wave in late diastole. The transcutaneous

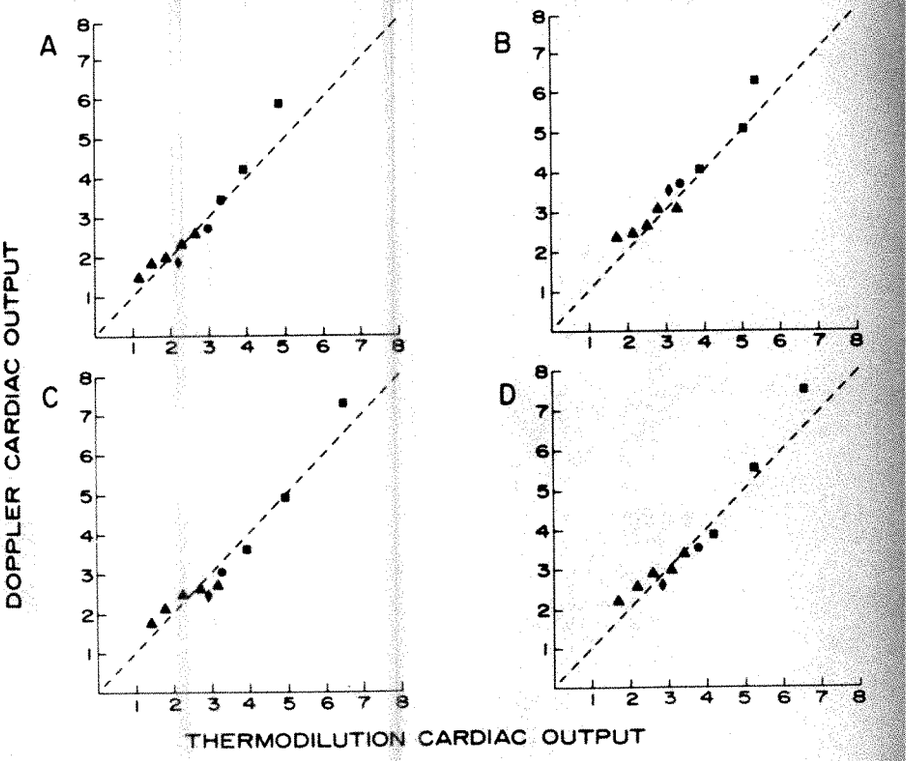

FIGURE 3. The values for cardiac output measurements (in liters/min) obtained by the Doppler method plotted against simultaneous thermodilution values for four representative dogs under the various hemodynamic conditions of the protocol. For dog A, the correlation coefficient (r) = 0.97, slope = 1.16, y intercept = 0.29; for dog B, r = 0.97, slope = 1.01, y intercept = 0.23; for dog C, r = 0.96, slope = 1.04, y intercept = −0.10; and for dog D, r = 0.96, slope = 1.07, and the y intercept = −0.09. **triangles** = hemorrhage; **diamonds** = propranolol; **circles** = baseline; **squares** = dopamine infusion.

Doppler velocity waveform and that produced by the electromagnetic catheter flow probe were generally similar in shape and magnitude in the baseline state, after 500 ml hemorrhage and at various stages during reinfusion, during the administration of dopamine at each of the three infusion rates and after administration of propranolol. However, the onset, duration and point of zero flow were slightly different with the two techniques, probably because, unlike the electromagnetic flow waveform, the Doppler signal represents the root-mean-square value for velocity (Fig. 1). This was exaggerated during dopamine infusion and after a premature ventricular beat. The reason for this exaggeration is unclear, but may be due to turbulence produced with more rapid ejection during dopamine infusion and after a premature beat, which would broaden the spectrum of frequencies detected by the Doppler instrument.

Comparison of cardiac output values: Cardiac output values ranged from 1.2 liters/min after 500 ml hemorrhage to 7.6 liters/min during maximal dopamine infusion. Figure 2 shows the correlation between values calculated from the Doppler velocity integrals and from the thermodilution method in all 20 dogs in the baseline state. In Figure 3, the values from four representative dogs are shown under various hemodynamic conditions. The average correlation coefficient of the regression lines for all 20 dogs was 0.92 (range 0.86 to 0.98). The values obtained after 500 ml hemorrhage and during the 16 μg/kg per min infusion of dopamine are farther from the line of identity than are those measured during the baseline state, during reinfusion of blood or after administration of propranolol. This proved to be a function of heart rate, as shown in Figure 4, in which the differences between the Doppler and thermodilution values are plotted against the heart rate; the most rapid rates occurred after 500 ml hemorrhage and during the 16 μg/kg per min infusion of dopamine. Results from other studies[4] have indicated that this inaccuracy of the Doppler method is probably a result of turbulent flow.

Experiments in Open Chest Dogs

Comparison of juxta-aortic Doppler and cuff electromagnetic flow probe signals: The velocity signal of the Doppler instrument and the signal produced by the electromagnetic cuff flow probe were similar in shape and magnitude, except that the peak of each Doppler signal occurred approximately 0.08 second after the peak "flow" signal.

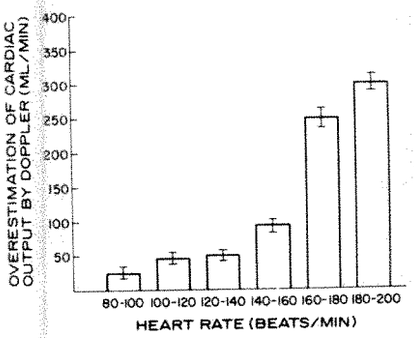

FIGURE 4. The differences (in ml/min) between Doppler and thermodilution values for cardiac output are shown for all 20 dogs at various ranges of heart rate. At higher heart rates the Doppler values overestimated thermodilution values more than at lower heart rates. Values are mean ± standard error.

FIGURE 5. Simultaneous signals produced by transcutaneous and juxta-aortic Doppler probes with the same amplification and identical 75 cm/s calibrations. ECG = electrocardiogram.

Comparison of transcutaneous and juxta-aortic Doppler signals: The velocity signals recorded transcutaneously and from within 1 cm of the wall of the aorta were nearly identical except for a lower signal to noise ratio in the transcutaneous signal, a result of the distance between the probe and the aorta and the movement of the chest wall and lungs in the artificially ventilated dogs (Fig. 5). This similarity held true under all hemodynamic conditions and at all heart rates encountered.

Simultaneous transcutaneous Doppler, juxta-aortic Doppler and cuff flow probe: When the three methods of estimating stroke volume were performed simultaneously, it was possible to determine the factors related to the greatest variance between Doppler estimations of stroke volume (by either method) and cuff flow probe measurements. Figure 6 shows stroke volumes calculated from both Doppler signals plotted against the stroke volumes measured by cuff flow probe. At very low and very high stroke volumes, both Doppler methods tended to overestimate the cuff flow probe value; however, the standard error of the estimate was still small (less than 4.3 ml) so that a high degree of accuracy was present throughout the range of stroke volumes. The percent of measured stroke volume estimated by both Doppler methods was found to be inversely proportional to the preceding R-R interval (Fig. 7), an observation that is consistent with the errors noted after an extrasystolic beat and at rapid heart rates. Thus, rapid heart rates and not absolute stroke volume appear to be major limitation of the method in the anesthetized dog.

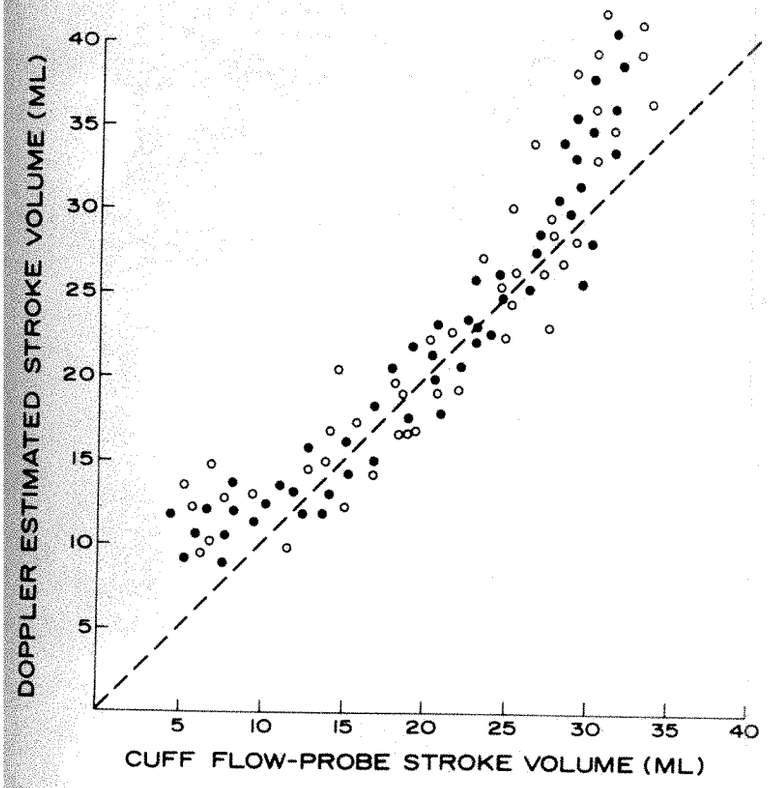

FIGURE 6. Comparison of stroke volumes (in ml) in one dog as measured by the Doppler technique and cuff flow probe. **Open circles** = transcutaneous probe; **closed circles** = juxta-aortic probe. To better demonstrate the differences encountered at very low and very high stroke volumes, correlation analyses were separated for the 5 to 15 ml, 15 to 25 ml and 25 to 35 ml range of stroke volumes. For 5 to 15 ml, the correlation coefficient (r) = 0.61, slope = 0.48, y intercept = 8.01, and the standard error of the estimate (SEE) = 3.3 ml; for 15 to 25 ml, r = 0.86, slope = 1.11, y intercept = −2.28 and SEE = 1.6 ml; for 25 to 35 ml, r = 0.77, slope = 1.78, y intercept = −19.12 and SEE = 4.3 ml.

Discussion

This study of 20 closed and open chest dogs demonstrated the usefulness of the method of estimating cardiac output by multiplying the 1 minute sum of Doppler velocity integrals in systole by the cross-sectional area of the proximal aorta. The method was accurate for estimating stroke volume in most hemodynamic situations except at extremely rapid heart rates and after an extrasystolic beat. We have also shown that Doppler signals recorded with the transducer outside the thoracic cage are almost identical to signals recorded with the probe 1 cm from the aortic wall, except for greater noise in the transcutaneous signal.

• **Physical and physiologic considerations:** There are theoretical reasons why a measurement of instantaneous blood flow velocity should parallel flow or cardiac output measurements by any other method. The forms of the velocity profile created by a pressure gradient that oscillates sinusoidally have been described in mathematical terms.[5] The pressure gradient is assumed to be the form $M \cos(\omega t - \psi)$, the standard expression for one harmonic component of a Fourier series. The equation

$$\frac{\partial U}{\partial t} = -\frac{1}{\rho}\frac{\partial p}{\partial \chi} + \nu\left(\frac{\partial^2 U}{\partial r^2} + \frac{1}{r}\frac{\partial U}{\partial r}\right)$$

describes the behavior of the axial (forward) velocity (U) as a function of the radius (r) of the vessel, time (t), the density of blood (ρ), and the kinematic viscosity (ν) when blood is subjected to an oscillatory pressure gradient. The geometric form of the oscillatory profile is well known[6] and helps to explain why problems in measurement arise in certain situations. The velocity at the aortic wall is zero (or near zero) and a boundary layer formed just distal to the aortic leaflets gradually grows in thickness until the flow in the entire aorta is influenced by this phenomenon of viscosity and the velocity distribution assumes a parabolic form. The flow velocity in the center of the aorta is then greater than at the aortic root in order to preserve continuity. The point at which this occurs is called the "inlet length" and changes throughout the cardiac cycle.[7] By taking velocity measurements from the proximal aorta, this problem of the parabolic profile is avoided, except at extremely low heart rates.

The equations that describe the characteristics of oscillatory flow in a tube are not precisely applicable to aortic flow because the aorta is distensible. The distensibility is complicated by (1) viscoelastic behavior that is responsible for attenuation of the pulse wave traveling from the heart, and (2) by a nonlinear response in resisting different degrees of arterial distension. However, the importance of this distensibility is more theoretical than functional, since Bernouilli's theorem: $p_o = p + \frac{1}{2}q^2\rho$ (where p_o is the uniform stagnation pressure of the flow, q is velocity, p is the hydrostatic pressure and ρ is the density of blood) relates pressure and velocity such that a flow curve (velocity curve) can be calculated from a pressure gradient measured in the proximal aorta.[8] This is particularly important because two of the three dimensions (cross-sectional area) we are using to calculate cardiac output have the capacity to change through systole, thus affecting the calculation of flow. Greenfield and Patel[9] have shown that the average change in aortic cross-sectional area during systole is 11 percent. In the dog aorta, the cross-sectional area is sufficiently small that the absolute error (in cm^2) would be acceptable for calculations of flow from area and linear velocity, particularly with the constraining effects of the cuff flow probe. However, in the human aorta, the area is larger (from 4.5 to 8.5 cm^2) and the pulse rate is slower than in the dog, so that absolute errors in area are much more important.

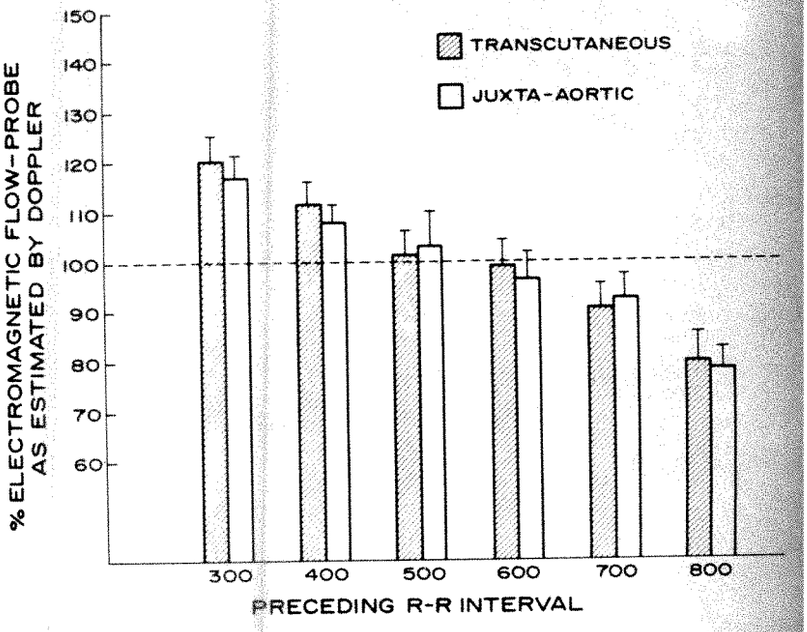

FIGURE 7. Graph depicting the percentage of flow probe stroke volume estimated by both Doppler probes at different preceding R-R intervals (in ms).

Clinical implications: If the method for estimating cardiac output and stroke volume using the integral of Doppler velocity signals during systole and the cross-sectional area of the aortic root is to be used in human studies, several factors must be considered: (1) a method for measuring the cross-sectional area of the aorta and accounting for systolic change will be required for accurate calculations; (2) in patients with multiple premature ventricular beats during the study, cardiac output calculated from Doppler velocity integrals will underestimate the true value; and (3) clinical situations associated with marked tachycardia may cause Doppler stroke volume estimations to be greater than the true value. These problems notwithstanding, the overall method appears to be extremely promising for clinical use.

Transcutaneous Doppler Method of Measuring Cardiac Output—II

Noninvasive Measurement by Transcutaneous Doppler Aortic Blood Velocity Integration and M Mode Echocardiography

JOHN R. DARSEE, MD
PAUL F. WALTER, MD

with the technical assistance of
DAVID E. CLAPHAM, MSEE

Atlanta, Georgia

In 15 patients with acute myocardial infarction (group I) and in 14 patients undergoing routine cardiac catheterization (group II) cardiac output values obtained by multiplying the 1 minute sum of the systolic integral of aortic blood flow velocity by the average systolic diameter of the aortic root were compared with values obtained with the thermodilution and Fick methods, respectively. Patients in group I were studied under various hemodynamic conditions, whereas those in group II were studied in the baseline state only. In group I, the correlation between the two methods was excellent (r values ranged from 0.96 to 0.99) except in one severely anemic patient whose Doppler signals were noisy, but at heart rates exceeding 150 beats/min it was not as good. In group II, the correlation between the two methods was r = 0.96 with a standard error of the estimate of 0.226 liter. The Doppler method is totally noninvasive and is useful for monitoring changes in cardiac output in patients with acute myocardial infarction.

A simple, accurate noninvasive method is needed for monitoring cardiac function in critically ill patients, particularly those with acute myocardial infarction. The state of the myocardium in these patients is in constant flux because of changing quantities of ischemic tissue and labile blood pressure and heart rate. Methods requiring a pulmonary arterial thermodilution catheter are hazardous in patients with coagulation abnormalities and are technically difficult in some situations. Echocardiography is a useful noninvasive method of assessing cardiac output but cannot be performed adequately in all patients. A noninvasive method for continuously monitoring hemodynamic data would be of considerable utility when administering antiarrhythmic agents, colloid and crystallized solutions, vasodilators and positive inotropic drugs.

Transcutaneous continuous wave Doppler measurements of aortic ejection velocity have been shown to approximate closely the velocity values obtained with invasive methods.[1,2] Relative changes in the integral of the velocity signal in systole have also been shown to correlate with changes in stroke volume over a wide range of cardiac output values in dogs.[3] Encouraged by these observations and by our own studies in dogs,[4] we investigated the possibility of using transcutaneous continuous wave Doppler ultrasound to measure absolute values of cardiac output in hemodynamically unstable patients with acute myocardial infarction, and in patients in stable condition undergoing diagnostic cardiac catheterization.

Methods

Patients

Group I—coronary care unit: Group I consisted of 12 men and 3 women (mean age 54, range 36 to 67 years) with acute myocardial infarction. All had historical, electrocardiographic and creatine kinase isoenzyme criteria for acute infarction and were studied in the coronary care unit of Grady Memorial Hospital or the Atlanta Veterans Administration Hospital. Materials required for studies

From the Department of Medicine (Cardiology), Emory University School of Medicine, Atlanta, Georgia. This study was supported in part by a Grant-in-Aid from the American Heart Association (Georgia Chapter), Atlanta, Georgia. Manuscript received October 2, 1979; revised manuscript received April 21, 1980, accepted April 29, 1980.

Address for reprints: John R. Darsee, MD, Cardiovascular Research Laboratory, Harvard Medical School, 180 Longwood Avenue, Boston, Massachusetts 02115.

in group I included a triple lumen flow-directed catheter (Edwards Laboratory), Edwards Laboratory digital thermodilution cardiac output computer (model 9510-A), 2 continuous-wave directional Doppler units (Sonicaid Corp; Bach-Simpson Ltd.) with 2.0 and 2.2 megahertz unfocused transducers and an Ampex multichannel instrumentation recorder.

Group II—cardiac catheterization laboratory: Group II consisted of 10 men and 4 women (mean age 50, range 32 to 58 years) undergoing diagnostic cardiac catheterization for chest pain in the Grady Memorial Hospital Cardiac Catheterization Laboratory. In group II the Doppler unit was connected to an eight channel recorder (Electronics for Medicine) with light-sensitive paper (Kodak® Linagraph). A Swan-Ganz flow-directed catheter and an angiographic pigtail catheter were placed in the pulmonary artery and thoracic aorta, respectively, to sample blood for the Fick determination.

Informed written consent was obtained from all 29 patients for the Doppler determination and for placement of the thermodilution pulmonary arterial catheter in group I and for the entire catheterization procedure with angiography in group II.

Cardiac Output Measurements

Determination of cardiac output standards: In group I the pulmonary arterial thermodilution catheter was inserted at the time of admission to the hospital. Cardiac output was determined by averaging the results of values obtained after three 10 ml bolus injections of dextrose in water cooled to 5° C.[5] These values were not known to the investigators until after all data were collected and the Doppler values calculated. In group II the Fick cardiac output was measured utilizing a 3 minute collection of expired gas (Douglas bag) analyzed for oxygen and carbon dioxide content using the Scholander technique, with simultaneous samples of anticoagulated blood drawn over a 90 second time period from the pulmonary artery (10 ml) and the aorta (10 ml). The pulmonary and systemic arterial whole blood oxygen contents were measured with the Van Slyke technique, and the arteriovenous difference was calculated by subtraction. Cardiac output (CO) was calculated using the standard formula:

$$CO\ (\text{liters/min}) = \frac{\text{Oxygen consumption (ml/min)}}{\text{Systemic arteriovenous oxygen difference (ml/liter)}}$$

Determination of aortic cross-sectional area: In each patient, an M mode echocardiogram of the aortic root and leaflets was performed before or during Doppler measurements (Fig. 1). Greenfield and Patel[6] showed that the average change in the cross-sectional area of the human proximal aorta during systole was 11 percent. We[7] have confirmed their observations using echocardiography as the method of measurement. Therefore, we used a method of determining the average systolic diameter from the aortic root echo, rather than merely using half the sum of end-diastolic and end-systolic diameters (Fig. 2). The average systolic cross-sectional area ($\bar{A}$) of the aortic root was calculated using the formula: $\bar{A} = \pi(\frac{1}{2}\bar{D})^2$ where $\bar{D}$ is the average aortic diameter.

Doppler velocity measurements: Doppler velocity measurements were made simultaneously with cardiac output determinations using the thermodilution technique in group I and during blood sampling in group II. For velocity measurements of blood flow in the proximal aorta, the continuous wave Doppler transducer was placed in the suprasternal notch and directed inferiorly toward the patient's left hip until a velocity signal was detected with peak flow toward the transducer. The transducer was rotated clockwise until the probe direction resulting in the greatest peak velocity (usually between 75 and 125 cm/s) was obtained. This method of aligning the probe was used in both groups. The reliability of obtaining nearly identical velocity tracings in the same patient was tested by removing the probe, replacing it, again locating the probe position resulting in the greatest peak velocity and comparing the signals. In each case there was less than 5 percent difference between the mean of 30 sequential values for peak velocity before and after the probe was moved.

Studies in the cardiac catheterization laboratory allowed further localization of the region of the proximal aorta from which Doppler velocity measurements were being made. Once the probe was aligned to detect maximal peak velocity, small quantities of contrast dye were injected into the proximal aorta under fluoroscopic control until the audio frequency produced by the Doppler instrument became lower in pitch and coarse in quality and coincided with the onset of dye ejection from the catheter. This region was always within 3 cm of the aortic root. Similar injections of dye into the brachiocephalic vessels were not detected with the Doppler instrument, indicating that subclavian and carotid flow velocities were not contaminating the aortic velocity measurements.

The Doppler shift frequencies detected with the ultrasonic probe were processed with a zero-crossing detector system and

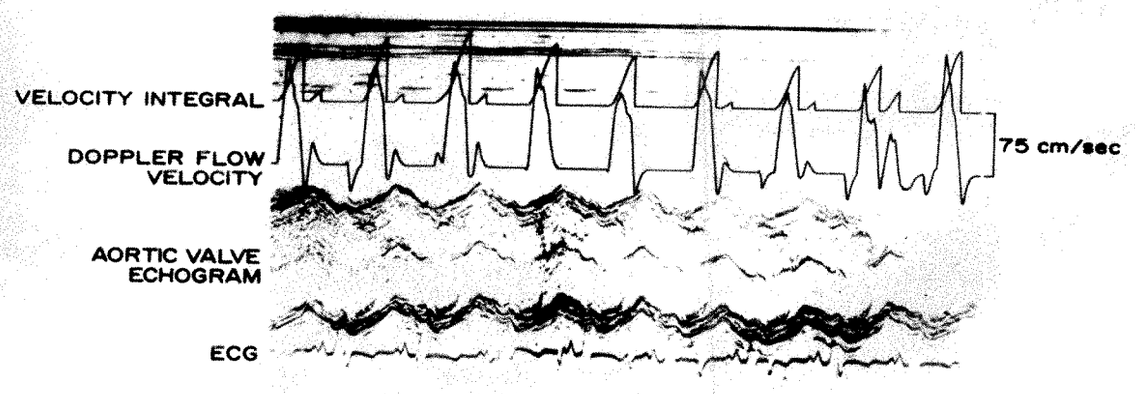

FIGURE 1. Simultaneous M mode echocardiogram of the aortic root, the aortic valve and continuous wave Doppler signals of flow velocity in the proximal aorta and electrocardiogram (ECG). The velocity integral is the electronic integration of the area beneath the systolic portion of the velocity signal above zero flow. The velocity integral (proportional to stroke volume) changes with respiration.

converted to an analog voltage signal. Zero flow (velocity) and signals of 50 and 100 cm/s were produced by the Doppler instrument electronically for calibration. Each raw velocity signal was recorded and simultaneously integrated to produce a signal that represented the area confined below each velocity curve and above zero flow. The electrocardiogram, velocity signal and velocity integral were recorded on an Electronics for Medicine eight channel recorder using light-sensitive paper (Kodak Linagraph), or were first recorded on a multichannel instrumentation recorder (Ampex®) and later replayed for permanent records.

Study protocol: In group I, velocity signals and thermodilution cardiac output values were measured soon after each patient was admitted to the coronary care unit. Depending on the baseline hemodynamic values (pulmonary capillary wedge pressure, heart rate and cardiac output), colloid solution, sodium nitroprusside or dopamine, or any combination, was infused at a rate commensurate with the needs of the patient. Thermodilution values and Doppler velocity measurements were obtained every 4 hours and each time a new drug was given or the rate of infusion was changed. An average of six comparisons between thermodilution cardiac output values and cardiac output values calculated from velocity signals were made in each patient.

In group II, the velocity signals were recorded during the Fick cardiac output determination. No hemodynamic agents were given.

Calculation of cardiac output from velocity signals: For each comparison between Doppler velocity signals and the cardiac output standard (thermodilution or Fick), the mean systolic cross-sectional area of the aorta was multiplied by the sum of all velocity integrals recorded during a 1 minute period. For example, if the mean systolic cross-sectional area was 7.0 cm^2, and the sum of velocity integrals recorded in 1 minute was 500 cm (the integral of velocity in cm/s over time gives a value with the dimensions of length), the calculated cardiac output would be 7.0 $cm^2 \times 500$ cm or 3,500 cm^3 (3.5 liters/min). Any integrals of velocity occurring in diastole were ignored in these calculations because diastolic "velocity" in the aorta represents the movement of blood that has already been ejected and therefore already measured.

Statistical analysis: The sequential values for calculated cardiac output determined from Doppler velocity signal integration and the echocardiographic mean aortic systolic cross-sectional area were compared with values measured with the thermodilution method separately in each patient in group I. Correlation analysis was used because comparison of data points between patients under different hemodynamic situations is not statistically valid. A correlation coefficient, slope, y intercept of the regression line and standard error of the estimate were computed for the series of measurements in each patient. In group II, cardiac output values were measured once in each patient in the baseline state only; a linear regression analysis was applied to the data in this group of patients.

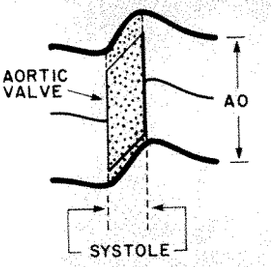

FIGURE 2. Diagram depicting the method of determining the average systolic diameter of the aortic (AO) root. The **shaded area,** which represents the time-integrated sum of all instantaneous systolic diameters, is measured with planimetry and then divided by the systolic ejection time to obtain the average diameter.

Results

Group I—coronary care unit: Velocity signals were obtainable in all 15 patients; they were reproducible during any one period of measurement and were generally smooth and uniform in shape. The time required to locate the probe position that produced the maximal peak velocity averaged 60 seconds; the longest time required was 2 minutes, 15 seconds in a patient who initially would not lie still.

During the infusion of dopamine at the rate of 14 μg/kg per min in one patient, the velocity signal was rough, presumably because of the associated pulse rate of 156 beats/min. At lower infusion rates, the problem

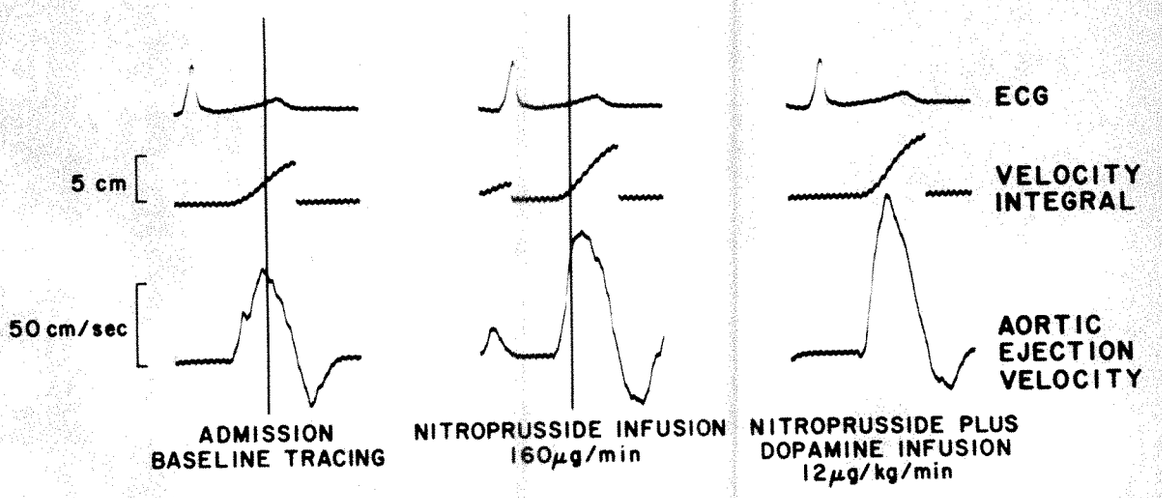

FIGURE 3. Patient C. The electrocardiogram (ECG), velocity integral and aortic ejection velocity are shown at the time of admission, 4 hours later with nitroprusside infusion, and 8 hours later with both a dopamine and a nitroprusside infusion. Both the peak velocity and the velocity integral increased after a single intervention and then after combined pharmacologic interventions.

was not encountered. A similar problem occurred in a severely anemic patient before transfusion and in a febrile patient before the body temperature was lowered. Figure 3 is a representative tracing showing the velocity signals recorded from one patient under three hemodynamic conditions. The comparison of calculated and measured cardiac output values for each patient is shown in Figure 4, and further details are given in Table I. There was generally an excellent correlation between the two methods except in Patient D, who was anemic (hematocrit = 22 percent) and had marked tachycardia (more than 160 beats/min) during all measurements. The standard error of the estimate ranged from 0.004 liter to 0.129 liter in these 15 patients.

Group II—cardiac catheterization laboratory: Velocity signals obtained in group II were also smooth and of uniform size and shape. All patients had a heart rate at rest of less than 100 beats/min, a hematocrit value greater than 35 percent and a basal body temperature of less than 38° C. Fick cardiac output values and those calculated from velocity signals are compared in Figure 5. The correlation coefficient, slope, intercept and standard error of the estimate are given in the figure legend; however, additional (and perhaps more practical) information is shown in the figure itself by the two curved lines that represent the 95 percent confidence limits for measurements in each cardiac output range. The distance between the lines of each point on the abscissa is therefore a function of the predictive value of the Doppler method under these conditions and in this laboratory. Although the confidence limits were wider at low and high cardiac output values, the error of the Doppler estimation was only 0.3 liter at the highest cardiac output value and only 0.2 liter at the lowest level of cardiac output. Thus, even at the two extremes of the curve, the accuracy of the Doppler method is sufficient for clinical use.

Conditions producing Doppler signals with a low signal to noise ratio: We noted three situations that seemed to produce rough velocity signals with considerable noise: (1) fever (temperature more than 39° C), (2) anemia (hematocrit less than 26 percent), and (3) rate of dopamine infusion (more than 14 μg/kg per min). Further evaluation revealed a common factor; the heart rate in each situation was more than 150 beats/min. This was best demonstrated in two patients with noisy signals receiving dopamine infusions of 16 and 18 μg/kg per min and with heart rates of 172 and 158 beats/min, respectively. When the infusion rate was lowered to 12 μg/kg per min, the heart rate in both patients decreased to less than 150/min. Velocity signals became much less noisy, uniform in shape and of smooth configuration. The same sequence of events occurred in the patients with fever or anemia in whom signal noise almost disappeared when these problems were treated. Values in Patient A (Fig. 4) represent measurements made after the fever was eliminated. However, in Patient D, the measurements were made while the patient was still anemic because matched blood was not available for 48 hours.

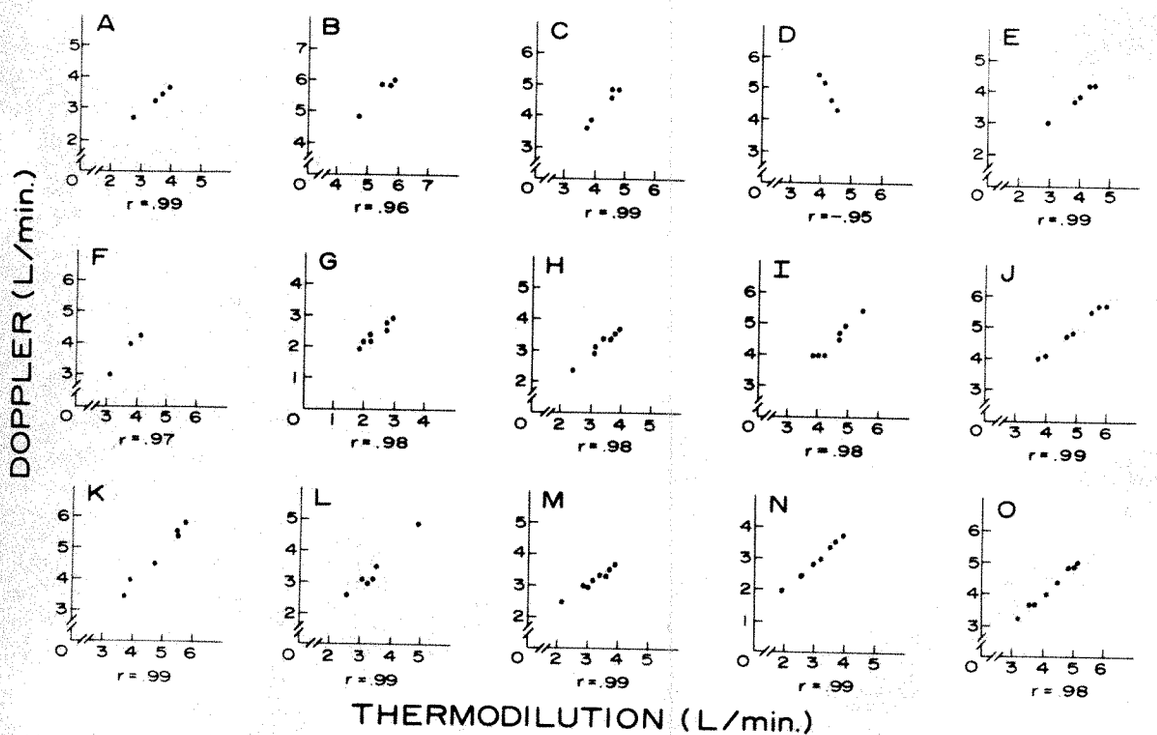

FIGURE 4. Linear regression plots of cardiac output values calculated from the Doppler velocity signals versus simultaneous values obtained with thermodilution in 15 patients (group 1). The correlation coefficient for each patient is shown below each plot. These values were obtained at the time of admission (usually the lowest value), and during dopamine or nitroprusside infusion, or both.

Discussion

Light[8] first described the application of the Doppler principle for the noninvasive measurement of instantaneous blood velocity in the proximal aorta of human subjects. The wave forms he obtained were similar to those established with invasive flow probe techniques. He described the method of placing the transducer in the suprasternal notch to record flow patterns in the aorta. The development of a direction-resolving circuit that introduced a phase shift before detection made possible the identification and separation of positive and negative Doppler shifts, that is, forward and backward flow.[9] Huntsman et al.[10] recorded aortic blood flow velocities in human subjects and obtained reproducible patterns from both the ascending aorta and the aortic arch.

The transcutaneous Doppler method has also been used to assess relative changes in stroke volume. Colocousis et al.[3] demonstrated that continuous wave Doppler ultrasound could estimate stroke volume changes in dogs subjected to several hemodynamic interventions that caused cardiac output to vary over a wide range. These investigators demonstrated a close correlation between the integral of the velocity signal and stroke volume as measured with standard thermodilution techniques. Studies in our laboratory[4] have confirmed their observations.

Clinical application: The results of previous studies using the Doppler method in both animals and human beings, plus the results of this study in patients, clearly demonstrate the potential of this procedure in the initial evaluation and hourly monitoring of patients whose condition is hemodynamically compromised. In previous reports[1,3,8,10] relative changes in blood velocity or stroke volume were assessed without assigning actual quantitative units to the results. Our study demonstrates that in many patients cardiac output (in liters/

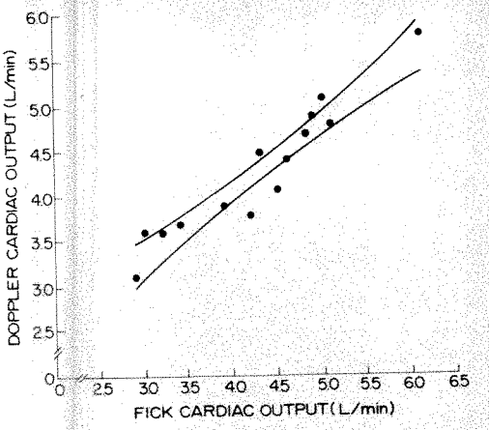

FIGURE 5. Cardiac output values obtained with the Fick and Doppler methods are plotted for each of the 14 patients in group II. The two lines represent the 95 percent confidence limits for the equation: $y = a + bx$, where y = Fick value, a = 1.02, b = 0.76, and x = measured Doppler value for cardiac output. The correlation coefficient for the regression line is 0.96 and the standard error of the estimate is 0.226 liter.

min) can be determined with a sufficiently small error to be useful in clinical practice.

In most patients the velocity profile in the proximal aorta is almost flat over most of its cross section and reproducible results are not critically dependent on the aim of the ultrasonic beam if its direction is approximately tangential to the course of the vessel.[11] The basic Doppler equation, $v = \Delta fc/2f_0\cos\theta$,* indicates that flow velocity can be calculated from the observed Doppler shifts with an accuracy of ±10 percent if the beam is within 25° of the direction of flow because of the small variation of $\cos\theta$ when θ is near 0. For the measurement of volume flow (Q), the Doppler equation must be multiplied by the cross-sectional area (A) of the vessel: $Q = (A)\ (\Delta fc)/(2f_0\cos\theta)$. The mean frequency shift (Δf) in this case is the average over the total vessel lumen; and θ is the average angle over the total lumen.

*c = sound velocity; f = the Doppler shift (Hz); f_0 = the center frequency (Hz); θ = the angle between the beam vector and velocity; and v = flow velocity.

Advantages: The Doppler method has several advantages over catheterization techniques for the repeated measurement of cardiac output: (1) A single unit can be used on multiple patients; (2) it carries none of the risks of indwelling catheters; (3) it does not require blood samples (as does the Fick method) or expansion of the intravascular volume (as does the thermodilution technique) that may present problems when serial studies are performed; and (4) the technique can be learned and used with accuracy and safety not only by cardiologists and cardiovascular surgeons, but also by nurses and technicians.

This study was performed to determine the interobserver variance for the interpretation of segmental thallium-201 image scores and the changes in such scores between the exercise and delayed images. Fifty patients, 40 with and 10 without significant coronary artery disease, underwent thallium imaging immediately after exercise and 2 hours later in the anterior and 50° left anterior oblique projections. The left ventricle was divided into six segments and graded by four independent observers on a scale of 0 (minimal activity) to +2 (normal activity). Interobserver variance was determined for each segment. For a change in thallium activity between exercise and delayed images, the interobserver variance was greatest for the apical and apical-inferior segments, intermediate for the inferior and septal segments and least for the anterolateral and posterior segments.

When segmental thallium scores were interpreted by an individual observer using a standard method employing one set of arbitrary criteria (method 1), the thallium stress test had a sensitivity of 77 percent and a specificity of 75 percent for coronary artery disease. When the scores were interpreted by an individual observer using criteria derived from interobserver variance analysis (method 2), the sensitivity increased to 86 percent (probability [p] <0.05); the specificity (78 percent) did not change significantly. When multiple observers arrived at a single diagnosis by consensus (method 3), the sensitivity was 75 percent and specificity 90 percent. However, when the multiple observers' scores were averaged and the averaged scores interpreted by a single set of criteria applied to all six ventricular segments (method 4), the sensitivity and specificity increased to 90 percent ($p < 0.05$ and not significant, respectively [method 4 versus method 1]). Thus, there is considerable interobserver variance in the qualitative scoring of segmental thallium activity. More caution must be observed in interpreting changes in activity from exercise to delayed images in the apical and apical-inferior segments than in the anterolateral and posterior segments. When only one observer is available, diagnostic accuracy is improved by using criteria based on interobserver variance analysis. However, when feasible, thallium stress tests should be interpreted by multiple observers because averaging of the multiple observers' scores maximizes both sensitivity and specificity.

Exercise thallium-201 myocardial perfusion imaging has been used extensively for the diagnosis of coronary artery disease.[1-9] Pohost et al.[10] demonstrated the resolution of some defects present on initial postexercise thallium images when patients underwent further imaging several hours after a single dose of thallium. Exercise image defects that disappeared were believed to represent transient ischemia whereas defects that persisted were thought to represent scar. Despite the increasing use of thallium myocardial imaging, the interobserver variability in the

qualitative assessment of thallium activity has not been well defined. Trobaugh et al.[11] demonstrated the effect of this interobserver variance on the overall interpretation of the thallium study. Thus, the precision and diagnostic accuracy of these tests depends on this variability. Furthermore, because a consensus interpretation by multiple observers has been used in most studies of the diagnostic accuracy of the thallium stress test for coronary artery disease, the diagnostic accuracy for a single observer remains to be determined. This study was undertaken (1) to determine the interobserver variance in the qualitative scoring of segmental thallium myocardial activity, (2) to determine the diagnostic accuracy of a single observer's interpretation of thallium stress and delayed images, and (3) to evaluate the usefulness of several techniques designed to minimize the loss of diagnostic accuracy due to interobserver variance.

Methods

Study patients: The study group consisted of 50 patients (40 men and 10 women) who had thallium stress tests ordered by their private physicians for the evaluation of chest pain, and who subsequently underwent cardiac catheterization. Their mean age was 54 ± 9 (standard deviation) years (range 31 to 66).

All patients had selective coronary angiograms recorded with 35 mm cinematography at 60 frames/s. The angiograms were interpreted by two observers who arrived at a consensus diagnosis without knowledge of the results of thallium imaging. Significant coronary artery disease was defined as 50 percent or greater narrowing of at least one major coronary artery in at least two projections. Forty patients had significant coronary artery disease and 10 did not. Thallium stress tests were performed within 1 week of cardiac catheterization.

Thallium-201 image acquisition: Before exercise, a supine 12 lead electrocardiogram was obtained and an intravenous cannula was placed in a dorsal hand vein. Patients were stressed in the supine position with use of a bicycle ergometer. We routinely use either supine bicycle or treadmill exercise for thallium stress tests at our institution and have found no difference in the diagnostic accuracy of the two techniques.[3,9] Supine exercise was used in this study so that imaging could be initiated immediately after the end of exercise. Electrocardiographic lead II was monitored continuously and selected leads were recorded at 2 minute intervals. The initial exercise work load was 150 kilopond-meters (kpm)/min and increased by 150 kpm/min every 2 minutes. Exercise was symptom-limited by chest pain, shortness of breath or leg fatigue. Approximately 30 to 60 seconds before the anticipated completion of exercise, 1.5 mCi of thallium-201 (New England Nuclear, North Billerica, Massachusetts) was injected intravenously. Immediately after the completion of exercise and 2 hours later, imaging was performed with the patient supine in the anterior and 50° left anterior oblique projections.

Images were obtained with a conventional Anger scintillation camera (Ohio Nuclear Series 420 Mobile Gamma Camera) interfaced with a mobile nuclear medicine computer system (MUGA-CART, Medical Data Systems, Ann Arbor Michigan). An all purpose, medium resolution collimator was used. A 30 percent energy window encompassing X-ray emissions at 60 to 80 keV was selected. Imaging time for each collection was 6 minutes. Data were collected in a 128 by 128 matrix-byte mode format.

Thallium-201 stress test: data analysis: The thallium images were viewed on a computer gray scale display for interpretation. Only the central portion of the thallium image containing the myocardium was displayed. The exercise and delayed images were displayed side by side for comparison. No other computer manipulations were performed. Each image was interpreted by four independent observers unaware of the patient's cardiac catheterization findings or clinical history. The ventricle was divided into anterolateral, apical and inferior segments in the anterior view, and septal, apical-inferior and posterior segments in the 50° left anterior oblique view (Fig. 1). These segments were believed to correspond to the distribution of the three coronary arterial systems.

Thallium activity in each segment was subjectively graded as 0, 0.5, 1.0, 1.5 or 2.0. For each image, the segment (or segments) that demonstrated the most intense and homogeneous thallium activity (that is, the most normal) was graded +2. Segments that demonstrated no activity were graded 0. Segments that demonstrated clearly reduced, yet not absent activity were graded +1. Segments demonstrating decreased transmural thickness compared with the normal segment were also graded +1, except for the apical, septal, and apical-inferior segments which can normally appear thin. Larger apical and apical-inferior defects were considered normal in ventricles believed to be dilated. Half-points in the scoring system were used when an observer thought that activity or thickness of a segment was intermediate between two grades.

Four methods for interpretation of scores were studied. These methods are summarized in Table I and are further explained as follows:

Method 1 (individual observer, standard criteria): Individual observers' scores were first interpreted using the following (standard) criteria: A transient defect was defined as an increase in grade of 1.0 or more from the exercise to delayed image for any of the six ventricular segments. If a defect in the anterolateral, inferior, septal or posterior segment was present

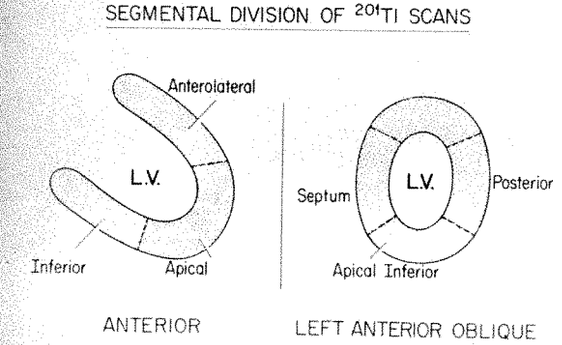

FIGURE 1. Schematic drawing demonstrating segmental division of thallium-201 images. L.V. = left ventricle.

TABLE I

Methods Used for Interpretation of Segmental Thallium-201 Image Scores

Method	Observers	Criteria Used
1	Individual	Standard
2	Individual	Interobserver variance analysis
3	Multiple (four) (consensus)	Standard
4	Multiple (four)	Average

at exercise (grade 1.0 or less) but did not increase by a grade of at least 1.0, it was considered a persistent defect. If a defect in the apical or apical-inferior segment was present at exercise (grade 0.5 or less), but did not increase in grade by at least 1.0, it was considered a persistent defect because these segments normally have less activity than that in the other four segments.

Method 2 (individual observer, interobserver variance analysis criteria): Interobserver variance analyses were performed for the six segments. On the basis of these results, criteria for the interpretation of segmental thallium scores were derived for each of the six ventricular segments (interobserver variance analysis criteria, Table II). Individual observers' scores were reinterpreted using these criteria.

Method 3 (multiple observers by consensus): The four individual observers' scores were used to arrive at a single interpretation for each patient by consensus. If at least three of four observers agreed on the presence of a defect, then the consensus was judged positive for coronary artery disease. Otherwise, the consensus was considered negative for coronary artery disease. The standard criteria were used for this analysis.

Method 4 (multiple observers, average criteria): The four observers' scores were averaged to yield a multiobserver score for each segment. These scores were interpreted using the following arbitrarily derived set of criteria (average criteria), which allowed smaller changes in scores to be considered significant than those of the standard criteria: A transient defect was defined by an increase in score of 0.5 or greater from the exercise to delayed image for any of the six ventricular segments. If a defect in the anterolateral, inferior, septal or posterior segment was present at exercise (grade 1.5 or less) but did not increase by a grade of at least 0.5, it was considered a persistent defect. If a defect in the apical or apical-inferior segment was present at exercise (grade less than 0.75) but did not increase by at least 0.5, it was considered a persistent defect because these segments normally have less activity than the other four segments.

With all four methods, a thallium stress test with at least one transient or persistent defect was considered positive for coronary artery disease.

Statistical analysis: Differences between the four individual observers' segmental scores and changes in these scores between exercise and delayed images were analyzed by a two-way analysis of variance. For the purpose of this study, the total estimated interobserver variance was defined as the error due to observer bias plus the random error inherent in the method. We expressed the estimated interobserver variance (s_{IO}^2) in terms of its associated standard deviation, that is, as $2 \times s_{IO}$ where the factor of 2 was chosen to give an approximate 95 percent confidence limit.[12] Variances were compared using an F test.

The sensitivity and specificity of the thallium stress test were defined as follows:

$$\text{Sensitivity} = \frac{\text{True positive tests}}{\text{True positive tests} + \text{False negative tests}}$$

$$\text{Specificity} = \frac{\text{True negative tests}}{\text{True negative tests} + \text{False positive tests}}$$

Sensitivity and specificity were calculated for each observer and then averaged to yield an overall sensitivity and overall specificity for the methods using individual observers. Sensitivity values for the four methods were compared by estimating the variance of the difference of these values with the use of a table of correlated proportions.[13] Each difference in sensitivity was then divided by the square root of this estimated variance (that is, by the estimated standard deviation of the difference in sensitivity values) to obtain a standard normal z variate. This z variate was then referred to a table of the cumulative normal distribution (area under both tails) to test the null hypothesis that the pair of sensitivity values were equal. The probability that the two values for sensitivity were equal, given the estimated z variate, was the conventional probability (p) value. Specificity values for the four methods were compared in the same manner.

Results

Interobserver variance in the scoring of segmental thallium-201 activity: Figures 2 and 3 demonstrate the interobserver variance in the scoring of segmental thallium activity for the exercise and delayed images and for the change in grade between the exercise and delayed images, respectively. The variance values were significantly higher for all exercise image segments ($p < 0.01$) than for corresponding delayed image segments, except for the apical segment. Those for the

TABLE II

Criteria for Interpretation of Segmental Thallium-201 Scores (scoring system from 0 to +2) Derived From Interobserver Variance Analysis

Interpretation	Left Ventricular Segment					
	AL	AP	Inf	Sep	AI	Post
Transient defect	$\Delta \geq 0.5$	$\Delta \geq 1$	$\Delta \geq 1$	$\Delta \geq 1$	$\Delta \geq 1$	$\Delta \geq 0.5$
Persistent defect*						
Exercise	≤ 1	$=0$	≤ 1	≤ 1	$=0$	≤ 1
Delayed	≤ 1.5	≤ 0.5	≤ 1.5	$\leq 1^{\dagger}$	≤ 0.5	≤ 1.5

* The criteria for a persistent defect require that conditions for both the thallium-201 image immediately after exercise (Exercise) and the image obtained 2 hours later (Delayed) be satisfied.

† Includes a delayed image score of 1.5 if the exercise image score is 1.

AI = apical-inferior; AL = anterolateral; AP = apical; Inf = inferior; Post = posterior; Sep = septal; Δ = exercise minus delayed image score.

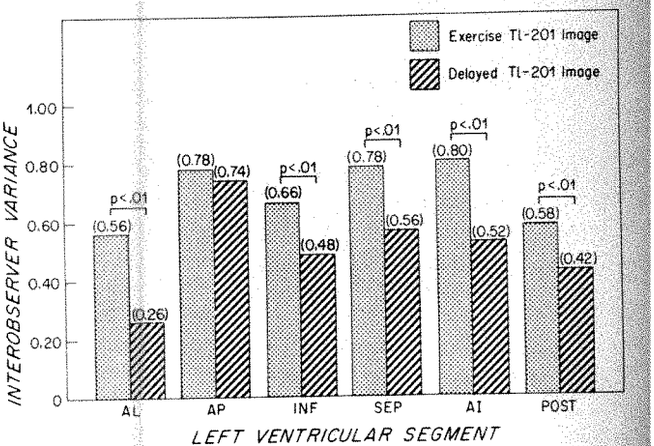

FIGURE 2. Interobserver variance in the scoring of left ventricular segmental thallium-201 (TL-201) activity for exercise and delayed images, expressed as 2 standard deviations (scoring system from 0 to +2). Left ventricular segments are anterolateral (AL), apical (AP), inferior (INF), septal (SEP), apical-inferior (AI), and posterior (POST). Comparisons among segments are discussed in text.

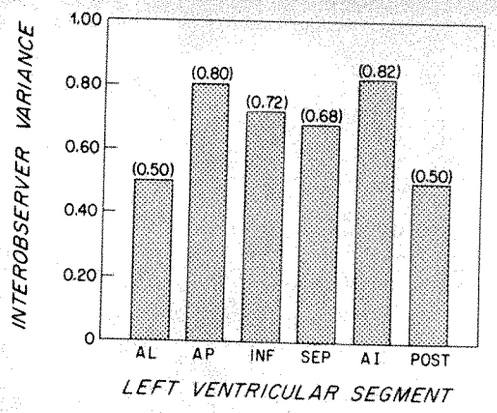

FIGURE 3. Interobserver variance in the scoring of changes in left ventricular segmental thallium-201 activity in exercise and delayed images, expressed as 2 standard deviations (scoring system from 0 to +2). Left ventricular segments as in figure 2. Comparisons among segments are discussed in text.

anterolateral and posterior segments in the exercise image were significantly lower ($p < 0.05$) than those for the other exercise image segments. The variance for the anterolateral segment in the delayed image was lower ($p < 0.01$) and that for the apical segment higher ($p < 0.01$) than that for all other delayed image segments. The variance values for a change in score between exercise and delayed images were lower for the anterolateral and posterior segments ($p < 0.01$) than for all other segments, and higher for the apical and apical-inferior segments ($p < 0.01$) than for all other segments except the inferior segment.

Table II lists the set of criteria (interobserver variance analysis criteria) for the interpretation of thallium scores derived from the interobserver variance values in Figures 2 and 3. For example, because the interobserver variance for change in thallium activity from an exercise to a delayed image is 0.5 for the anterolateral segment (Fig. 3), the interobserver variance analysis criteria require a difference in anterolateral exercise minus delayed image score (Δ) to be at least 0.5 for significance at the 95 percent confidence level. In this manner, the criteria have been individualized for each ventricular segment. The individual observers' scores were then reinterpreted using the interobserver variance analysis criteria (method 2) instead of the standard criteria (method 1). For example, one patient had an exercise anterolateral segment grade of 1.5 and a delayed anterolateral segment grade of 2.0. With use of the standard criteria, the anterolateral segment was interpreted as normal because a change in score of at least 1.0 was required for a transient defect. When these scores were reinterpreted using the interobserver variance analysis criteria, the anterolateral segment was interpreted as abnormal demonstrating a transient defect, because the change in score was at least 0.5.

TABLE III

Detection of Coronary Artery Disease With Thallium-201 Stress Test: Sensitivity and Specificity Using Four Methods of Interpretation

	Sensitivity (%)	Specificity (%)
Individual observer		
1. Standard criteria (method 1)	77	75
2. Interobserver variance analysis criteria (method 2)	86	78
		$p < 0.05$
Multiple observer		
1. Consensus* (method 3)	73	90
2. Average criteria (method 4)	90	90

* Three of four positive interpretations required for positive diagnosis.

Observer agreement in the overall interpretation of the thallium-201 stress test: *Method 1 (individual observer, standard criteria):* When the four observers' scores were individually interpreted using the standard criteria, the number of times that the observers agreed on the diagnosis regardless of the correct diagnosis was determined. There was complete observer agreement (four of four observers) in 29 (58 percent) of the 50 cases, partial observer agreement (three of four observers) in 13 cases (26 percent) and complete observer disagreement (two of four observers) in 8 cases (16 percent).

Method 2 (individual observer, interobserver variance analysis criteria): When the four observers' scores were individually interpreted using the interobserver variance analysis criteria, there was complete observer agreement in 35 (70 percent) of the 50 cases, partial observer agreement in 11 (22 percent) and complete observer disagreement in 4 (8 percent). The improved observer agreement using the interobserver variance analysis criteria compared with the standard criteria did not reach statistical significance (chi square = 2.06).

Sensitivity and specificity of thallium-201 test for coronary artery disease: Table III lists the sensitivity and specificity for coronary artery disease of the thallium stress test using the four different methods of interpretation.

Method 1 (individual observer, standard criteria): For an individual observer using the standard criteria, the overall sensitivity was 77 percent and the overall specificity 75 percent for coronary artery disease.

Method 2 (individual observer—interobserver variance analysis criteria): When the interobserver variance analysis criteria listed in Table II were applied to the individual observers' scores, the overall sensitivity increased to 86 percent ($p < 0.05$ compared with method 1). The overall specificity increased slightly to 78 percent (p = not significant compared with method 1).

Method 3 (multiple observers by consensus): When four observers used the standard criteria and arrived at a single diagnosis by consensus (three of four positive scores required for a positive diagnosis) the sensitivity was 73 percent and specificity 90 percent. These values were not statistically different from the values obtained with method 1.

Method 4 (multiple observers, average criteria): When the multiple observers' scores were averaged and the average scores interpreted with the average criteria, the sensitivity increased to 90 percent ($p < 0.05$ compared with method 1). The specificity also increased to 90 percent, although the difference from the value ob-

tained with method 1 was not statistically significant. Of the 40 patients with coronary artery disease, 9 had a transient defect alone, 8 had a persistent defect alone and 19 had both a transient and a persistent defect. Of the 10 patients without coronary artery disease, 1 had a transient defect, and none had either a persistent defect or both a transient and a persistent defect.

Discussion

Thallium myocardial perfusion imaging at rest has been used most extensively for the evaluation of patients with acute myocardial infarction,[14–18] unstable angina[19] and angina due to coronary arterial spasm.[20] Exercise thallium imaging has been used extensively for the diagnosis of coronary artery disease.[1–9] The precision of thallium imaging in diagnosing cardiac disease is dependent on interobserver variance in scoring and interpretation.

Interobserver variance in the scoring of segmental thallium-201 activity: Our results demonstrate the interobserver variance in the scoring of segmental myocardial thallium activity on exercise and delayed images. The values presented in Figures 2 and 3 represent estimated interobserver variance expressed as 2 standard deviations, which represent approximate 95 percent confidence levels for scoring thallium activity. Thus, the subjective grading of delayed image segmental thallium activity using a scoring system ranging from 0 to +2 is precise to within a grade of ± 0.26 to ± 0.74 depending on the segment analyzed (Fig. 2). Subjective scoring of exercise segmental thallium activity is precise to within a grade of ± 0.56 to ± 0.80 depending on the segment analyzed. The change in score between the exercise image and the delayed image is precise to within a grade of ± 0.50 to ± 0.82 depending on the segment analyzed (Fig. 3). Changes of less than these magnitudes fall within the range of interobserver variance and cannot be interpreted at the 95 percent confidence level. The higher variance values for the apical and apical-inferior segments are probably due to the wide spectrum of normal for these segments, because these segments can normally have decreased activity due to myocardial thinning. The overall lower variance values of the anterolateral and posterior segments compared with those of the inferior and septal segments may be due to higher target to background ratios for the first two segments. The outer edges of the anterolateral and posterior segments border the lungs, which have relatively low activity, whereas the outer edges of the inferior and septal segments border the right ventricle, which has relatively high activity.

Variance values were significantly higher for all exercise image segments (exept for the apical segment) than for corresponding delayed image segments. One explanation for this finding may be that the majority of defects were present in the exercise images, because many of them disappeared by the time of the delayed images. Thus, a greater proportion of the delayed images were completely normal and easier to score. Another explanation may be related to the increase in the background lung activity that occurs with exercise in some patients with coronary artery disease. This increased lung activity essentially disappears by the time of the delayed image. The decreased target to background ratio results in a reduction in image contrast in the exercise thallium image.

Observer agreement in the overall interpretation of thallium-201 stress tests: Our results demonstrate considerable interobserver variance in the overall interpretation of the thallium stress test. When the standard criteria and four observers were used, there was complete agreement on the overall diagnosis in 58 percent, partial agreement in 26 percent and complete disagreement in 16 percent of cases. Use of the interobserver variance analysis criteria increased complete agreement to 70 percent and decreased partial agreement and complete disagreement to 22 and 8 percent, respectively.

Other investigators have demonstrated considerable interobserver variance in the interpretation of the thallium stress tests. Trobaugh et al.,[11] using four observers, demonstrated "essentially complete" agreement on the overall diagnosis when the thallium images were interpreted twice by different observers. Lenaers et al.[1] using two observers, reported disagreement on the presence or absence of "hypoperfusion" in 7.5 percent of segments. Finally, Bailey et al.,[6] using two observers, reported disagreement on the significance of a change from exercise to rest in 14 percent of patients.

Sensitivity and specificity of the thallium-201 stress test for coronary artery disease: Our results demonstrate a sensitivity of 77 percent and a specificity of 75 percent for the thallium stress test in the detection of coronary artery disease when an individual observer uses the standard criteria (method 1). When an individual observer uses separate criteria derived from an interobserver variance analysis for each of the ventricular segments (method 2), the sensitivity increases to 86 percent ($p < 0.05$) with no significant change in specificity (78 percent). The increased sensitivity is accompanied by an increase in observer agreement and a decrease in observer disagreement. Thus, the use of criteria derived from an interobserver variance analysis allows for more sensitive interpretation of small changes in thallium activity scores without an attendant decrease in specificity.

When four observers used the standard criteria and arrived at a single diagnosis by consensus (method 3), the sensitivity was 75 percent and specificity 90 percent. Most previously reported studies have used the consensus interpretation of two to four observers and have reported similar values for sensitivity (range 56 to 95 percent) and specificity (range 88 to 97 percent).[1–8] In the present study, when the multiple observers' scores were averaged and the averaged scores interpreted by the average criteria (method 4), the sensitivity increased to 90 percent ($p < 0.05$) and the specificity remained at 90 percent. Thus, interpretation by multiple observers increases the diagnostic accuracy of the thallium stress test, possibly by averaging out isolated false diagnoses by individual observers.

Implications: There is considerable interobserver variance in the qualitative scoring of segmental thallium myocardial activity. This variance is particularly high

for scoring changes in activity between exercise and delayed images for the apical and apical-inferior segments. Thus, changes in activity for these two segments must be interpreted cautiously. The variance value is lowest for the anterolateral and posterior segments. Changes in activity for these two segments can be interpreted with greater confidence.

When only one observer is available, diagnostic accuracy is improved by the use of criteria for interpretation based on an interobserver variance analysis. When feasible, thallium stress tests should be interpreted by multiple observers because errors due to observer variance can be reduced and, thus, diagnostic accuracy improved. Averaging of the multiple observer scores and interpretation of the averaged scores using the average criteria appears to be more useful than interpretation by simple consensus.

The potential application of diagnostic ultrasound to understanding of the hemodynamic effects of various rhythm and conduction disturbances has not been fully explored. To investigate the changes in cardiac function associated with various atrioventricular (A-V) sequencing intervals during cardiac pacing, simultaneous M mode and two dimensional echocardiographic and hemodynamic studies were performed in 23 dogs.

One to one A-V and ventriculoatrial (V-A) sequential pacing at cycle lengths of 400 and 300 ms revealed a stepwise reduction in left ventricular pressure and cardiac output as the A-V interval was changed from +100 to −100 ms. These reductions in cardiac hemodynamics were associated with decreases in left ventricular and increases in left atrial dimensions determined with echocardiography. Mitral valve excursion and the duration of valve opening remained constant over the entire range of A-V intervals. There was angiographic evidence of retrograde blood flow from the left atrium into the pulmonary venous system at an A-V interval of −50 and −100 ms, but no evidence of mitral regurgitation.

Thus, correlative echocardiographic and hemodynamic studies can suggest multiple pathophysiologic mechanisms contributing to the decrements in cardiac function observed during tachyarrhythmias with intact A-V conduction as well as those occurring consequent to A-V nodal Wenckebach cycles.

Echocardiography has revealed abnormal and occasionally characteristic ventricular wall motion patterns in association with a variety of electrocardiographic abnormalities. These electrocardiographic changes include the alterations in conduction associated with left bundle branch block,[1–3] accelerated idioventricular rhythms,[4] preexcitation syndromes[5–9] and, most consistently, with ventricular ectopic beats.[10] Furthermore, patients with various forms of preexcitation may have such well defined wall motion abnormalities that these are virtually diagnostic for the ventricular site of insertion of the bypass tract.[4,5,9] Typically, left ventricular posterior wall bypass tracts are detected more consistently than are those coursing through the interventricular septum.[8,9]

Previous investigators[10,11] have also demonstrated the potential applications of echocardiography to understanding of the effects of various rhythm and conduction disturbances on cardiac performance. DeMaria et al.[12] assessed the contribution of atrial transport to ventricular function after electroconversion of supraventricular arrhythmias by evaluating motion of the mitral valve with echocardiography. Similarly, other investigators[13,14] described the echocardiographic manifestations of mitral valve and left atrial wall motion in the presence of atrial flutter.

From previous work we have had a particular interest in the hemodynamic sequelae of both supraventricular and ventricular tachycardias, and in the hemodynamic consequences of various cardiac pacing

methods.[15] Thus, the present studies were designed specifically to determine the echocardiographic correlates of changes in cardiac performance secondary to changes in atrioventricular (A-V) conduction patterns.

Methods

Experimental preparation: Twenty-three mongrel dogs weighing 13 to 20 kg were anesthetized with intravenous administration of 20 to 30 mg/kg of sodium pentobarbital (Nembutal®) and intubated. Ventilation was maintained by a Harvard respirator with use of room air. The chest was opened using a mid line incision and the pericardium was left intact. Left ventricular and aortic pressures were measured using a 7F Millar dual Mikro-Tip catheter pressure transducer (PC 771) inserted through the right femoral artery. Left atrial pressures were obtained using a 5F Millar Mikro-Tip catheter pressure transducer (PC 350) introduced through a pulmonary vein. Cardiac output measurements were made utilizing a Swan-Ganz thermodilution catheter and an Edwards 9510A cardiac output computer.

With use of 23 gauge needles, Teflon®-coated stainless steel unipolar plunge wire electrodes (0.1 mm diameter) were placed in the left atrial appendage and the myocardium of the left ventricular apex to pace the heart. The pacing stimuli were 1 ms in duration. Both atrial and ventricular pacing were applied using constant current pulses of twice diastolic threshhold. In addition, Teflon-coated, thin silver wire bipolar plunge electrodes were placed in the left atrial appendage and the left ventricular free wall in order to record the electrograms from each of these sites.

Echocardiography: M mode echocardiographic studies were obtained using a Smith-Kline Ekoline 20 interfaced with an Irex 101 Continutrace recorder. A 2.25 megahertz transducer was placed on a rigid bar that was attached to both sides of the surgical table. The methods of recording echocardiograms from the various cardiac structures were similar to those described by Kerber et al.[16] In four animals, two dimensional echocardiographic recordings were also obtained using a wide angle (90°) mechanical sector scan (Advanced Technology Laboratories, Mark III). The transducer was attached to the same bar assembly used for the M mode echocardiographic transducer.

In seven animals, an 8F catheter with multiple side holes at its tip was introduced into the left side of the heart through the left atrial appendage or retrograde through the femoral artery in order to obtain left atrial or left ventricular cineangiograms, or both, using hand injections of 5 ml of Renografin®. Contrast echocardiograms were obtained by bolus injection of saline solution directly into the left ventricle in order to determine the degree of mitral valve regurgitation.

Echocardiographic recordings of the left atrium, left ventricle, mitral and aortic valve opening were obtained during ventricular pacing at cycle lengths of 400 and 300 ms at multiple atrioventricular (A-V) intervals (+100, +50, 0, −50 and −100 ms). The echocardiographic correlate of A-V nodal Wenckebach periodicity was also evaluated in seven dogs during rapid atrial pacing at cycle lengths varying from 320 to 200 ms. Three dogs with stable, surgically induced A-V nodal heart block were studied during sequential pacing of the atria and ventricle at cycle lengths of 400 and 300 ms. The studies were repeated after the induction of atrial fibrillation

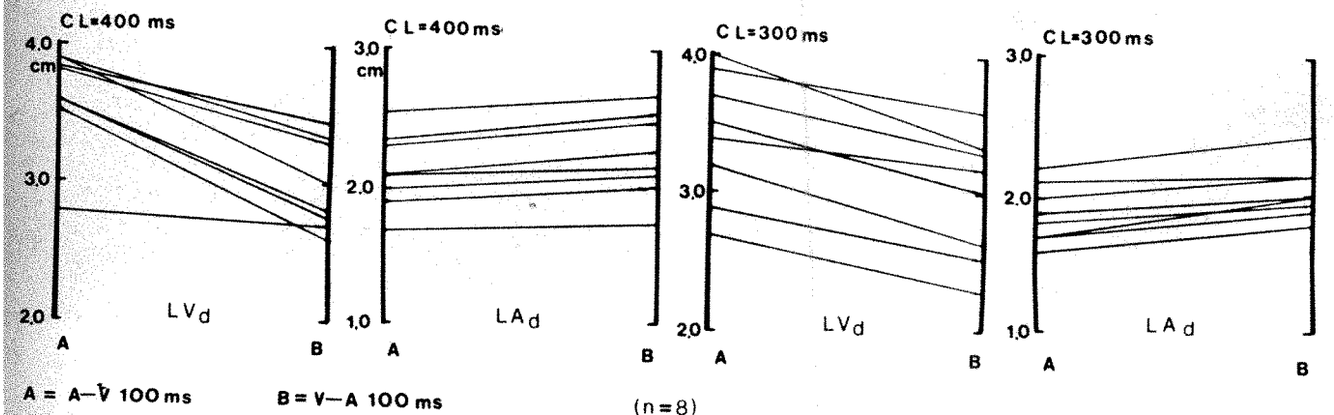

FIGURE 1. Left panels, changes in left ventricular (LVd) and left atrial dimensions (LAd) at end-diastole in centimeters are shown as the atrioventricular (A-V) pacing interval is changed from +100 ms (A) to −100 ms (B) at a cycle length (CL) of 400 ms. Note the reduction in left ventricular and increase in left atrial dimensions. **Right panels,** the same findings shown at a cycle length of 300 ms. V-A = ventriculoatrial.

and ventricular pacing at these same cycle lengths. One scalar electrocardiographic lead, left atrial, left ventricular and aortic pressures and the M mode echocardiograms were recorded simultaneously on an Irex 101 Continutrace recorder. Simultaneous electrocardiographic and pressure recordings were also obtained on a Hewlett-Packard eight channel photographic recorder (model 4578A).

Left ventricular and atrial dimensions were measured at maximal diameter. At least 10 beats were used in each record and all measurements were confirmed by two observers. Interobserver differences were within ±0.1 cm.

Results

1:1 Atrioventricular and Ventriculoatrial Pacing

• The effects of different atrioventricular (A-V) intervals on cardiac hemodynamics during A-V sequential cardiac pacing at cycle lengths of 400 and 300 ms in 15 dogs are shown in Table I. At both pacing cycle lengths there was a stepwise reduction in left ventricular pressure and cardiac output as the A-V interval was changed from +100 to +50, 0, −50 and −100 ms. These alterations in cardiac hemodynamics were associated with decreases in left ventricular and increases in left atrial dimensions determined with M mode echocardiography (Fig. 1). Figure 2 illustrates the echocardiographic alterations occurring during pacing at a constant cycle length of 400 ms when the A-V interval was changed from +100 ms (A) to −100 ms (B) (that is, ventriculoatrial (V-A) interval of 100 ms). In this representative case, left atrial dimension increased from 2.3 to 2.5 cm with a concomitant decrease in left ventricular diastolic diameter from 3.9 to 3.0 cm. At an A-V interval of −100 ms left atrial contraction occurred during the latter portion of the ventricular ejection period at a time when the A-V valves were still closed (Fig. 2B). At the shorter cycle length of 300 ms there was a similar increase in left atrial pressure and dimension and a decrease in left ventricular pressure and dimension as the A-V interval was decreased from +100 to −100 ms (Table I, Fig. 1).

Several other notable observations were made during these studies. Mitral valve excursion and the duration of valve opening remained constant over the entire range of A-V intervals studied and were independent of alterations in cardiac hemodynamics and chamber size (Fig. 3). Left atrial angiography was performed during each of these A-V sequencing intervals. Consistently, at A-V intervals of −50 and −100 ms, there was angiographic evidence of retrograde flow from the left atrium into the pulmonary venous system (Fig. 4) (that is, pulmonary venous regurgitation). Remarkably, there was no evidence of mitral regurgitation on left ventricular angiography or contrast echocardiography at any A-V interval

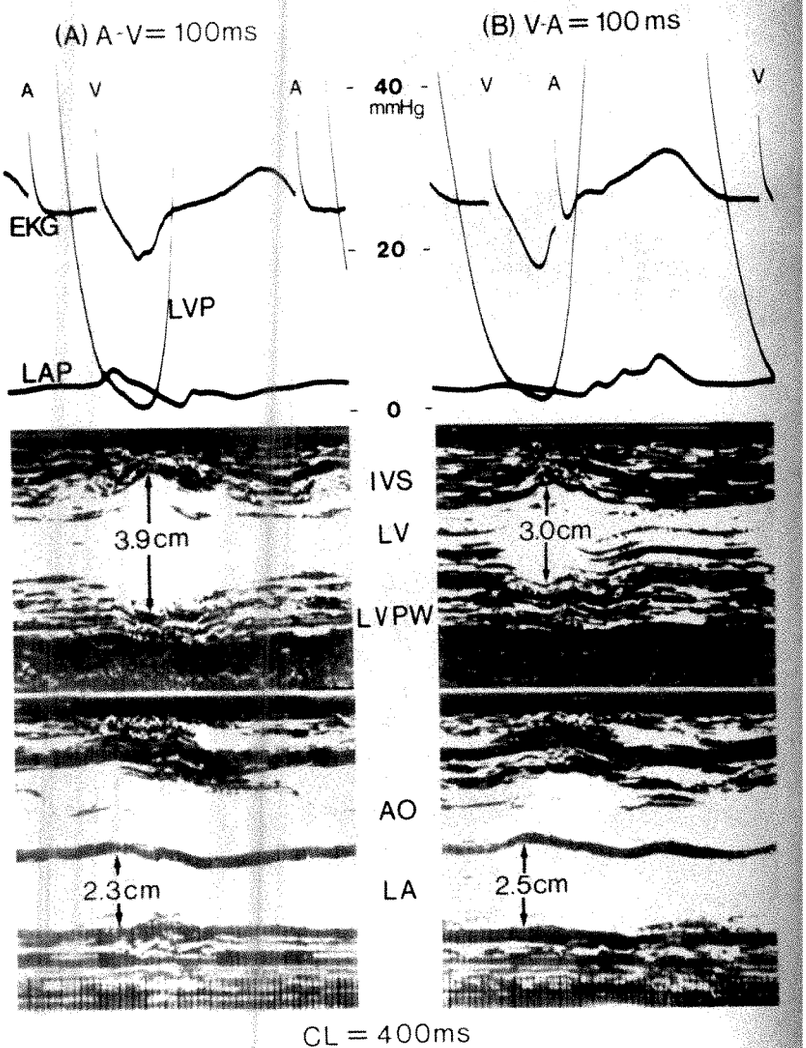

FIGURE 2. Representative study showing a marked decrease in left ventricular (LV) cavity size with a concomitant increase in left atrial (LA) dimension during abnormal atrioventricular (A-V) sequencing. **Top panel** shows the effects of an A-V interval of 100 ms at a cycle length (CL) of 400 ms in (**A**) and the effects of an A-V interval of −100 ms (V-A) in (**B**). Note the decrease in left ventricular (LV) dimension from 3.9 cm (**A**) to 3.0 cm (**B**) and an increase in left atrial (LA) dimension from 2.3 cm (**A**) to 2.5 cm (**B**). Also note the elevated left atrial pressure (LAP) during the left ventricular ejection period. A = atrial pacing spike; AO = aortic root; EKG = electrocardiogram; IVS = interventricular septum; LVP = left ventricular pressure; LVPW = left ventricular posterior wall; V = ventricular pacing spike.

during 1:1 A-V or V-A pacing at cycle lengths of 400 or 300 ms (Fig. 5, A and B). In addition, in three animals with surgically induced A-V heart block atrial fibrillation was induced by high frequency atrial pacing. Notably, in the presence of atrial fibrillation and A-V block there was also no evidence of mitral regurgitation during ventricular pacing at a fixed cycle length of 400 or 300 ms (Fig. 5C).

Rapid Atrial Pacing

Rapid atrial pacing at cycle lengths of less than 280 ms with 1:1 A-V sequencing usually resulted in both electrical and mechanical left ventricular alternans. In Figure 6 the mechanical systole after mitral valve opening and left ventricular filling was forceful and prolonged and resulted in aortic valve opening with a normal ejection period. This prolonged systole encroached on the next atrial contraction (arrow), resulting in an abortive attempt to open the mitral valve (asterisk). The next ventricular systole failed to open the aortic valve. However, this shorter systolic period engendered a more favorable A-V sequence that again enabled the mitral valve to open and facilitated left ventricular filling.

Rapid atrial pacing resulted in a Wenckebach pattern of A-V conduction (*Fig. 7*). During the prolonged pause that preceded the first conducted beat of each sequence, the lack of ventricular systole permitted an extended period of mitral valve opening and left ventricular filling. The next atrial contraction (single arrow) reopened the mitral valve and, further, actively filled the ventricle. All of these factors contributed to the subsequent enhanced and prolonged systole (360 ms) of the first conducted beat after the pause. The hemodynamic conditions preceding the second ventricular systole in the sequence (2) were much less favorable. The next

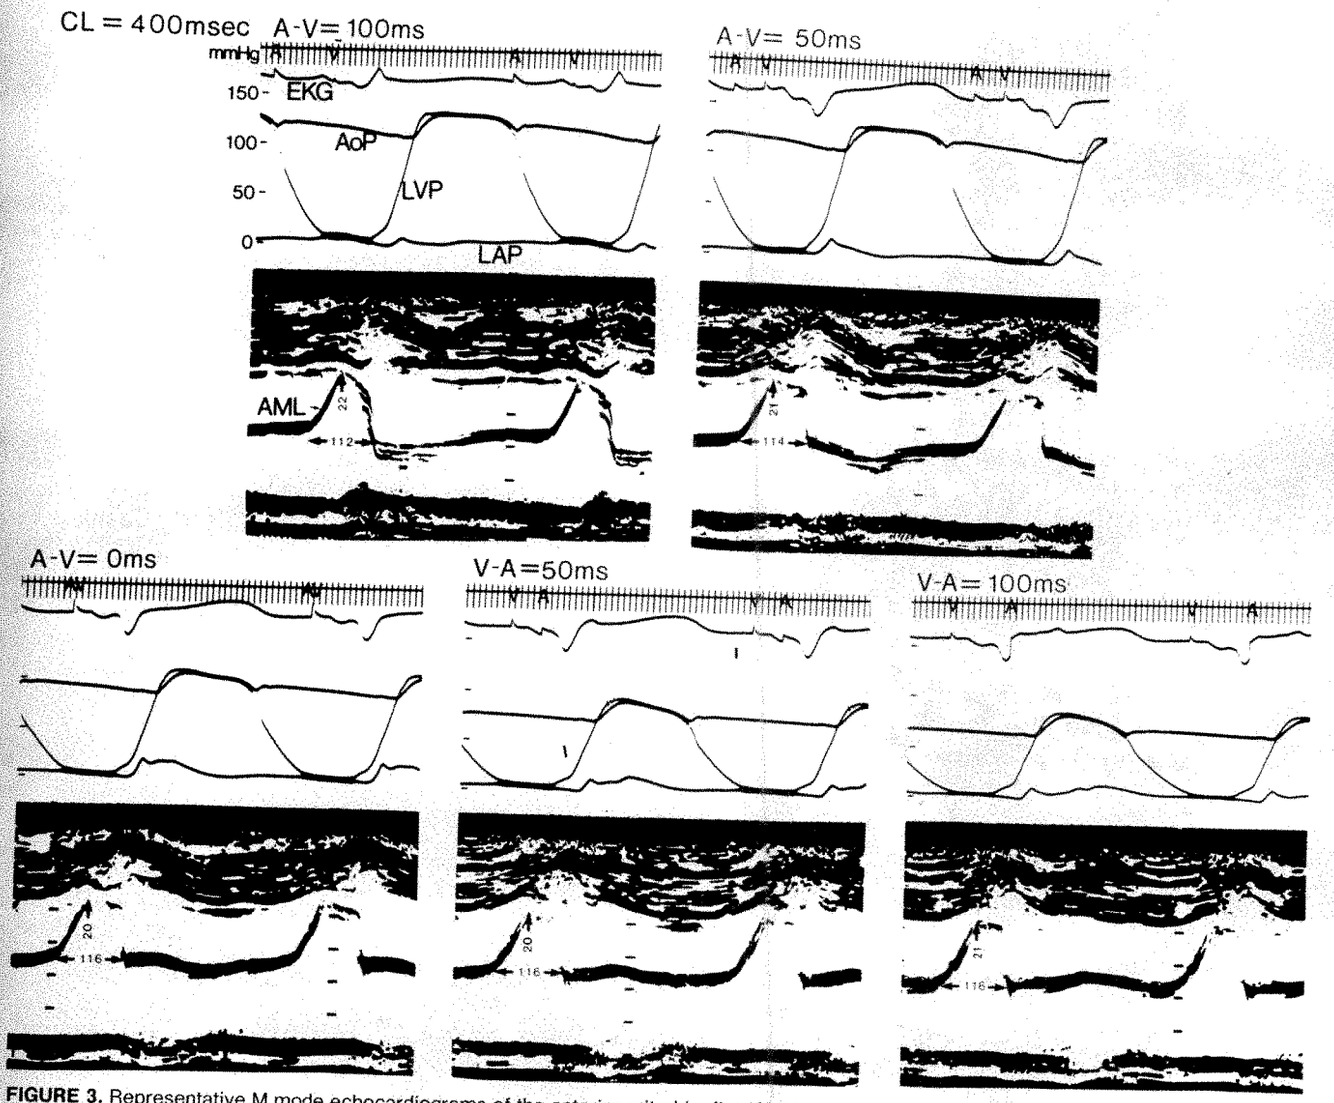

FIGURE 3. Representative M mode echocardiograms of the anterior mitral leaflet (AML) during various atrioventricular (A-V) and ventriculoatrial (V-A) intervals at a cycle length (CL) of 400 ms recorded with simultaneous pressure curves. The duration of mitral valve opening and the amplitude of excursion remain essentially constant. The numbers between two transverse arrows (←→) indicate the duration of diastolic opening of the anterior mitral leaflet in milliseconds and those under a single vertical arrow (↑) show the excursion of this leaflet in millimeters. Note the decrease in left ventricular (LVP) and aortic (AoP) pressures as the A-V interval was changed from +100 to −100 ms. A = atrial pacing spike; EKG = electrocardiogram; LAP = left atrial pressure; V = ventricular pacing spike.

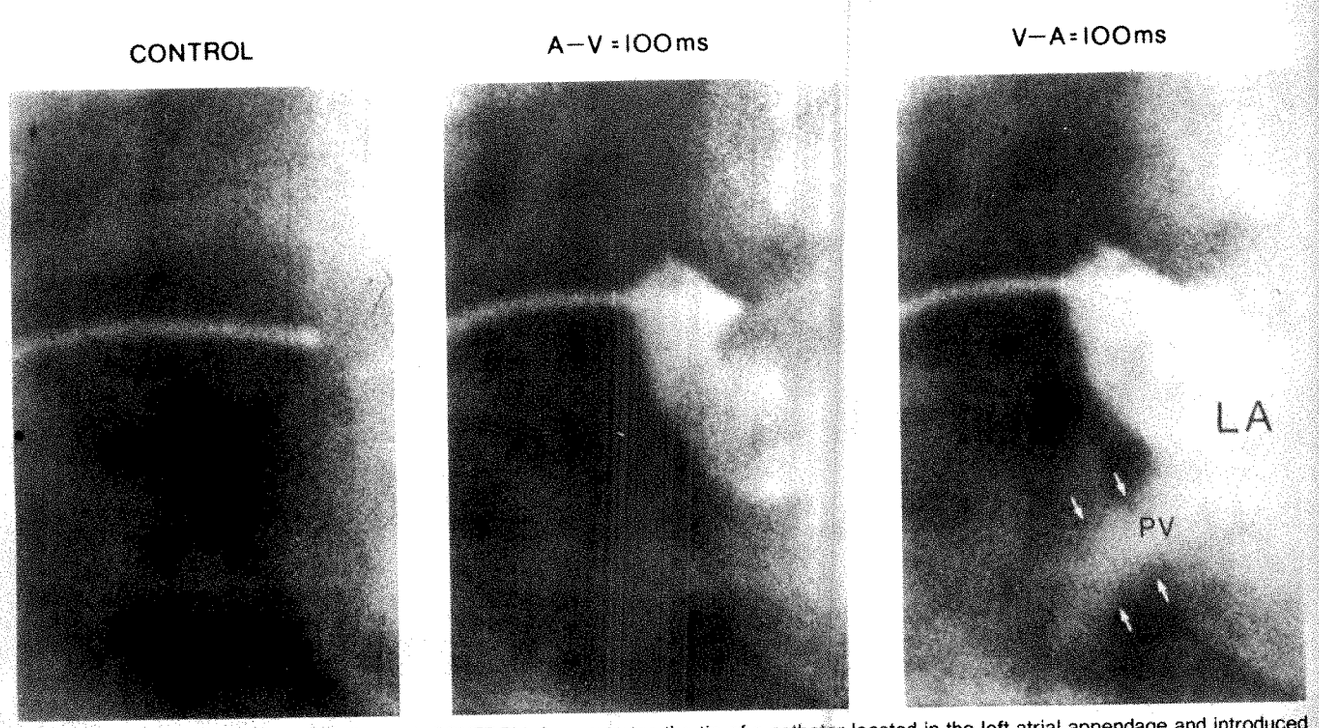

FIGURE 4. Left atrial angiograms. **Left panel** (CONTROL) demonstrates the tip of a catheter located in the left atrial appendage and introduced by way of the pulmonary vein. **Right panel** demonstrates marked regurgitation (**white arrows**) of contrast medium from the left atrium (LA) into the pulmonary vein (PV) during a ventriculoatrial (V-A) pacing interval of 100 ms at a cycle length of 400 ms. No such regurgitation is observed during an atrioventricular (A-V) interval of 100 ms at a cycle length of 400 ms (**middle panel**).

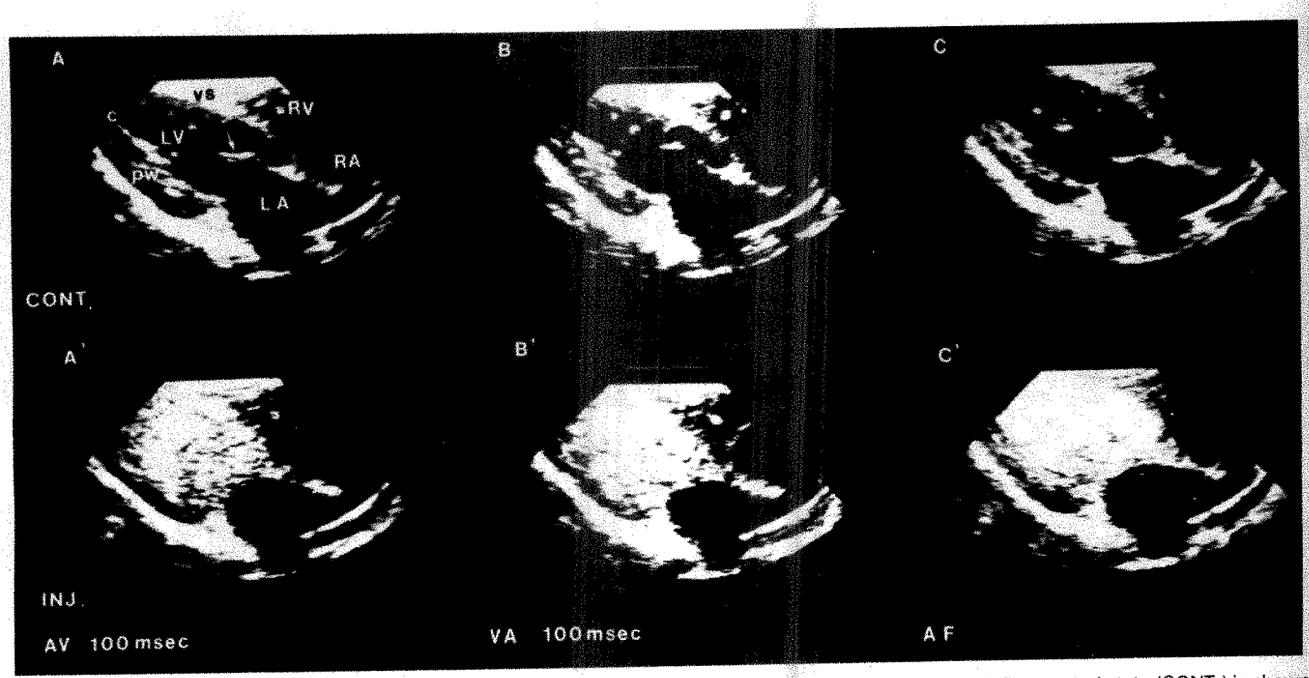

FIGURE 5. Still frames of a two dimensional echocardiographic left ventricular long axis view of a dog's heart. The control state (CONT.) is shown in the upper row (**A, B, C**) and systolic frames during saline injection (INJ) in the lower row (**A′, B′, C′**). **White arrow** in **A** indicates the anterior mitral leaflet. Changing the pacing sequence from an atrioventricular (A-V) interval of 100 ms (**A, A′**) to a ventriculoatrial (V-A) interval of 100 ms (**B, B′**) does not result in mitral regurgitation (that is, there are no saline microbubbles present in the left atrium in systole). Similarly, there is no evidence of mitral regurgitation in the presence of atrial fibrillation (A F) and A-V block with a constant ventricular rate (**C** and **C′**). LA = left atrium; LV = left ventricle; msec = milliseconds; pw = left ventricular posterior wall; RA = right atrium; RV = right ventricle; vs = interventricular septum.

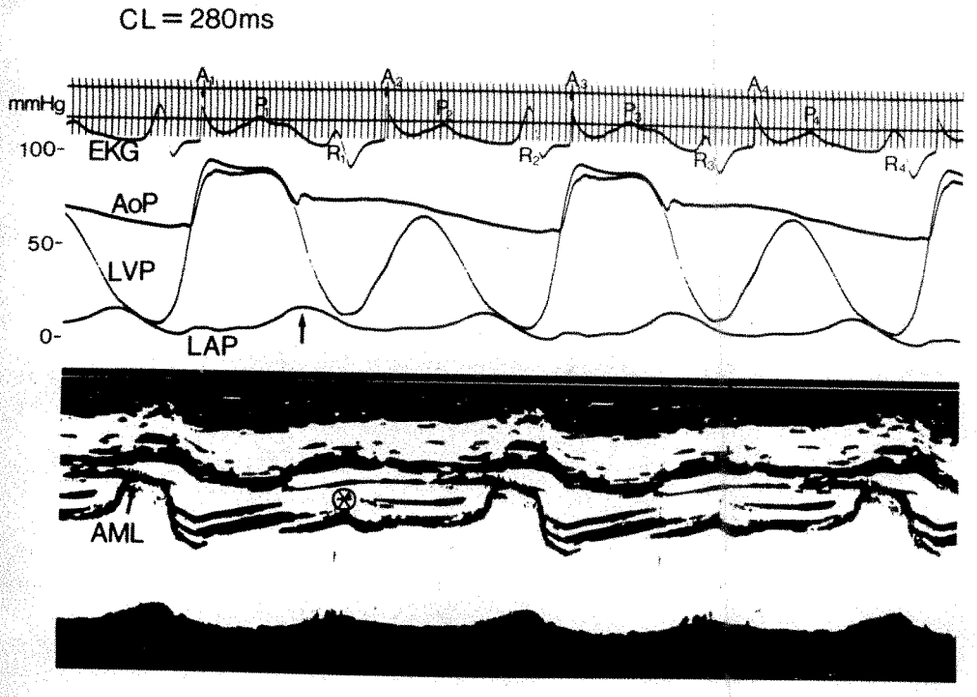

FIGURE 6. Rapid atrial pacing at a cycle length (CL) of 280 ms in this representative study shows the induction of left ventricular mechanical and electrical alternans. Pressure relations among the aorta (AoP), left ventricle (LVP) and left atrium (LAP) are shown in the **upper panel** and the echogram of the anterior mitral leaflet (AML) is shown in the **lower panel.** Note that the encroachment of the prolonged mechanical systole after the anterior mitral leaflet opening on the next atrial contraction (**black arrow** on the left atrial pressure curve) resulted in an abortive opening of the anterior mitral leaflet (**circled asterisk**). A = atrial pacing spike; EKG = electrocardiogram; P = P wave; R = QRS complex.

atrial contraction (double arrows) could not contribute to left ventricular filling because it occurred during ventricular systole. In addition, passive left ventricular filling as evidenced by mitral valve opening was shortened by encroachment of the next ventricular systole on the previous one, as dictated by the progressive shortening of the R-R intervals during typical Wenckebach sequences. The combination of these hemodynamic events resulted in a less powerful ventricular systole that failed to open the aortic valve.

The hemodynamic conditions became even more complex when rapid atrial pacing caused a combination of a 3:2 Wenckebach periodicity and an absolute 2:1 left ventricular and atrial alternans (Fig. 8). Because only every other electrical systole (R_1, R_4, R_7) resulted in a mechanical response, the passive mitral valve opening time was unusually prolonged. Atrial contraction after A_6 enhanced opening of the mitral valve (asterisk). Of note, because of the superimposed atrial alternans, effective atrial contractions occurred only

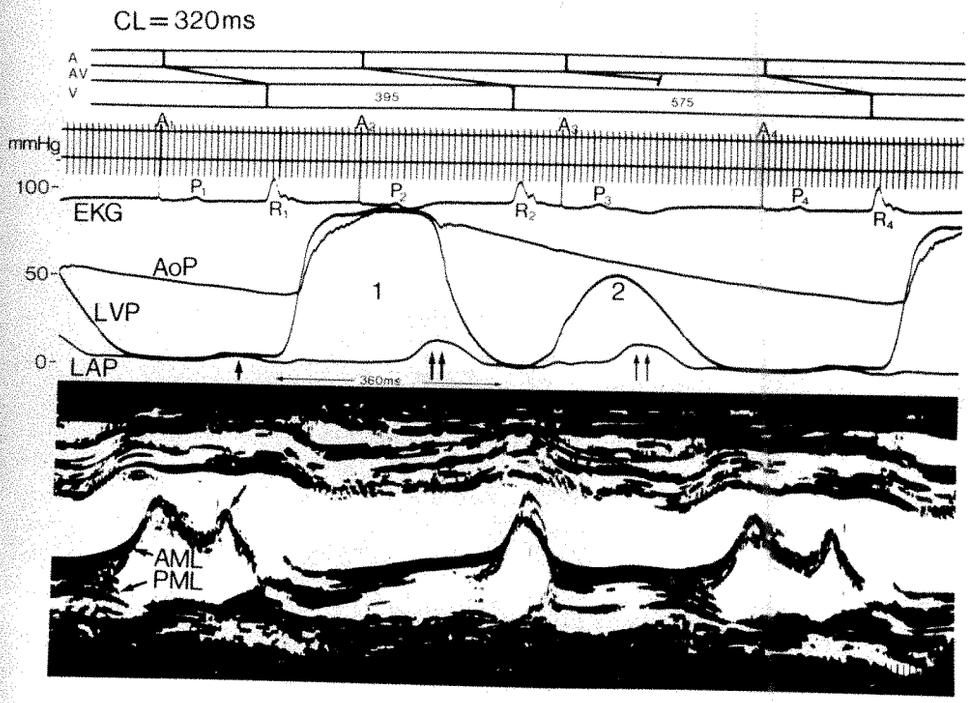

FIGURE 7. Rapid atrial pacing at a cycle length (CL) of 320 ms in a representative dog resulted in 3:2 Wenckebach periodicity. The ladder diagram depicts the conduction pattern. Note that the prolonged period of the mitral valve opening (**single arrow** on the echogram of the anterior mitral leaflet [AML]) after a dropped beat results in a forceful and prolonged (360 ms) mechanical systole (1), and that the passive left ventricular filling of this cycle is shortened because of the encroachment of the next ventricular systole (2) on the previous one (1). Also note that the atrial contraction varies depending on whether it occurs during the ventricular ejection period (**single** and **double arrows** on the left atrial pressure [LAP] tracer). A = atrial pacing spike; AoP = aortic pressure; EKG = electrocardiogram; LAP = left atrial pressure; P = P wave; PML = posterior mitral leaflet; R = QRS complex.

after each effective second ventricular systole (asterisk). Note the absence of the expected increase in atrial pressure (double arrows) during the ventricular ejection period and the closed mitral valve caused by the atrial alternans. Thus, although atrial contractions occurred at the same position in diastole during different cycles (arrow) they failed to open the mitral valve consistently.

Discussion

Alterations in cardiac function associated with various cardiac arrhythmias have previously been studied but have routinely been limited to measurements of traditional hemodynamic variables.[15,17] Using conventional methods, several investigators[15,17,18] have suggested that the hemodynamic consequences of various changes in the sequence of A-V activation and in the degree of irregularity of successive cardiac cycles may also result from secondary vasomotor and neurohumoral mechanisms. It has long been recognized[19] that the so-called atrial booster pump action present during normal A-V sequencing results in an increase in ventricular volume at end-diastole so that an approximately 10 to 20 percent larger cardiac output occurs than in the presence of A-V block. Furthermore, P wave synchronous pacing in complete A-V heart block results in a cardiac output approximately 10 to 15 percent greater than that with ventricular pacing at the same ventricular rates.[20]

Hemodynamic and chamber size alterations during A-V and V-A pacing: In a previous study,[21] we demonstrated that M mode echocardiography was useful in identifying the changes in cardiac function that occur in the presence of various patterns of A-V and V-A conduction. In this study, changes in cardiac hemodynamics and cardiac chamber sizes were evaluated by scanning the A-V interval from +100 to −100 ms in the presence of A-V and V-A sequential pacing. We observed progressive decreases in systolic blood pressure, cardiac output and left ventricular size concomitant with increases in left atrial size. As atrial systole moved into the period of mechanical ventricular systole, the contraction of the left atrium against the closed mitral valve resulted in marked regurgitation of blood into the pulmonary venous system (Fig. 4). Hence, it would appear that, in addition to the direct loss of the atrial contribution to ventricular filling, there was also a secondary and significant loss resulting from retrograde propulsion of blood during V-A conduction. Thus, even "stable" sustained ventricular rhythms with intact V-A conduction can result in serious hemodynamic consequences. In contrast, ventricular pacing or tachycardia in the presence of A-V block appeared hemodynamically relatively less deleterious because there was only a random rather than regular and inadvertent association of atrial and ventricular systole.[15] Similarly, the occurrence of atrial fibrillation in association with rapid ventricular rhythms was also apparently less deleterious hemodynamically than the presence of intact 1:1 rapid retrograde V-A conduction.[15]

Mitral valve function: Remarkably, the alterations in cardiac hemodynamics and changes in chamber dimensions during rapid 1:1 A-V pacing at various sequencing intervals were not reflected in the echocardiographic features of mitral valve function (Fig. 3). However, the variations in ventricular cycle lengths that

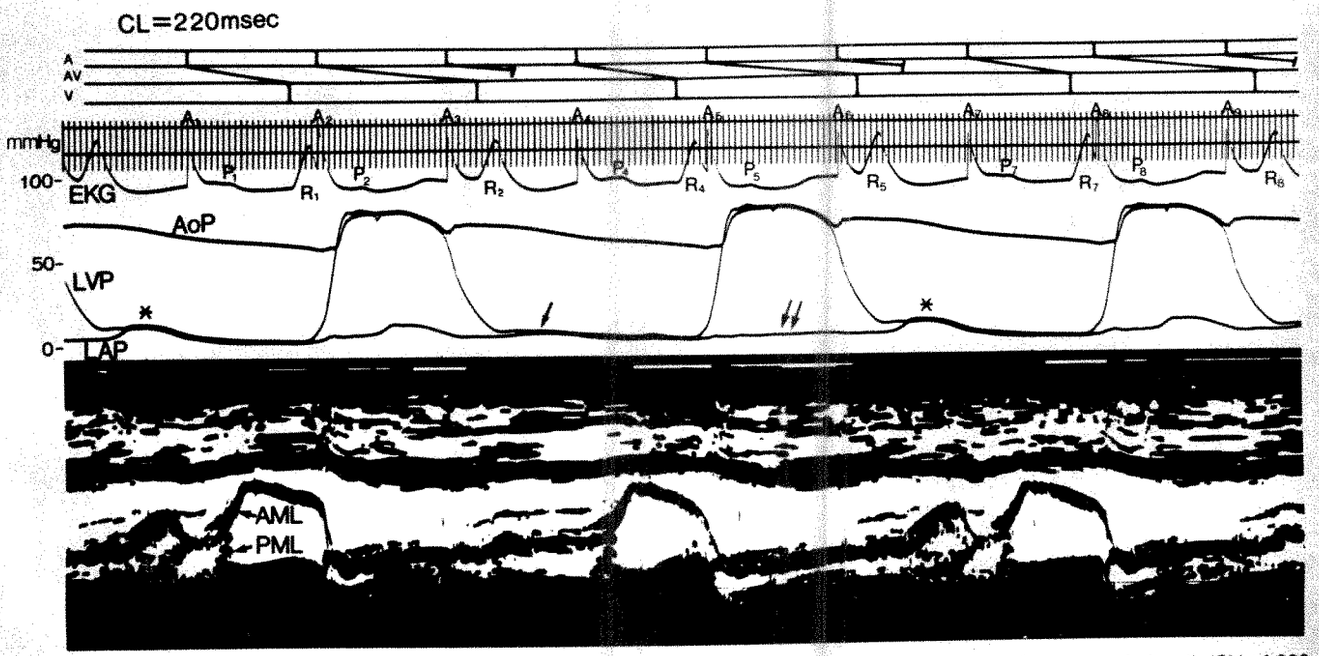

FIGURE 8. Wenckebach periodicity (3:2) with left ventricular and atrial alternans observed in a representative dog at a cycle length (CL) of 220 ms. The ladder diagram relates atrial pacing stimuli (A) to atrial activation (P) and ventricular activation (R). Aortic (AoP), left ventricular (LVP) and left atrial (LAP) pressures show complex patterns of left atrial and left ventricular alternans. Note the difference between the high (**asterisk**) and low (**arrows**) left atrial pressures. AML = anterior mitral leaflet; EKG = electrocardiogram; PML = posterior mitral leaflet.

occurred in association with progressive P-R interval prolongation during A-V nodal Wenckebach periods did affect mitral valve motion, and often obliterated the usual presystolic reversal of the A-V pressure gradient that normally places the A-V valve leaflets in a position to close early at the onset of ventricular systole. Hence, A-V valve regurgitation was observed during rapid atrial pacing causing Wenckebach periodicity and irregular R-R intervals (Fig. 9). Mitral regurgitation was never observed during sustained periods of V-A activation with constant P-R or R-P intervals as long as the R-R intervals remained constant (Fig. 5, A and B).[22] This was true even in the presence of atrial fibrillation in the dogs with heart block when the R-R intervals were kept constant (Fig. 5C).

Echocardiographic changes during Wenckebach conduction: D'Cruz et al.[23] observed that during 3:2 A-V Wenckebach conduction patterns, ventricular beats exhibited alternating long and short periods of systolic opening of the pulmonary and aortic valves and alternately large and small left ventricular stroke volumes. Left ventricular stroke volume in these cases appeared to be directly proportional to the preceding end-diastolic volume. Other investigators[24] observed alternating failure of mechanical responses to electrical depolarizations during A-V Wenckebach periods in addition to those ventricular contractions lost secondary to periodic A-V block, but the precise mechanism of this phenomenon has eluded clear definition. The echocardiographic observations made in our study have revealed an important mechanism contributing to the compromised hemodynamics during typical A-V Wenckebach periods in which R-R intervals shorten successively. At critical P-R and R-R intervals there is increasing encroachment of a subsequent atrial systole into the left ventricular ejection period of the previous systole. This successively shortens the duration of the opening of the mitral valve, abolishes active atrial transport and thereby reduces left ventricular filling. Other Wenckebach patterns might further compromise cardiac hemodynamics. However, the longer pause that follows the dropped beat does enable adequate mitral valve opening and left ventricular filling and thereby facilitates an effective subsequent beat (Fig. 7).

Clinical implications: As shown in the present study, echocardiography can provide considerable insight into the mechanisms responsible for the marked hemodynamic derangements that result from various patterns of A-V conduction. Such deleterious hemodynamic consequences could not be anticipated from

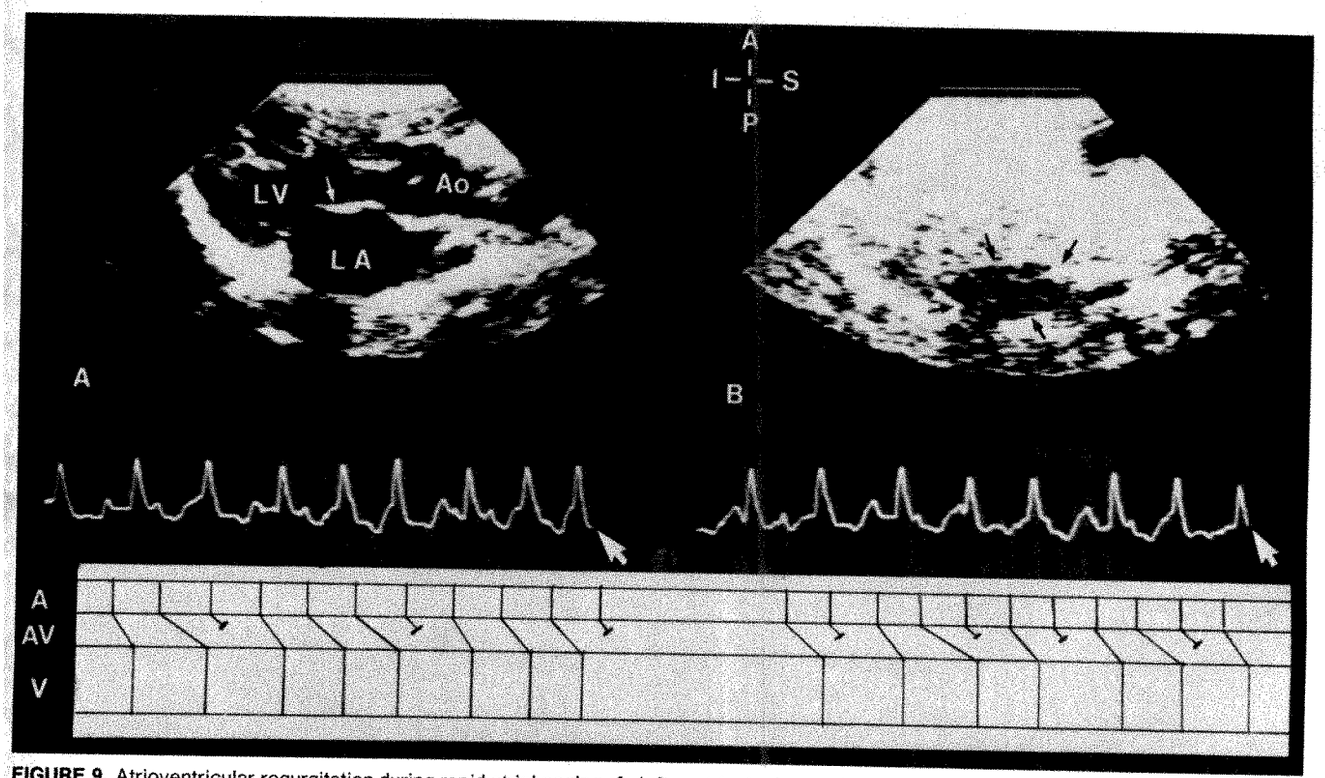

FIGURE 9. Atrioventricular regurgitation during rapid atrial pacing. **A,** left ventricular long axis two dimensional echocardiographic view of a representative dog heart during rapid atrial pacing causing Wenckebach periodicity. Ao = aorta; LA = left atrium; LV = left ventricle. The anterior mitral leaflet is marked by a **white arrow. B,** a still frame during systole of the same dog during saline injection into the left ventricle. Regurgitation of contrast medium into the left atrium is indicated by the **black arrows.** The **arrow** to the **right** of the electrocardiogram indicates the precise timing of the stop-frame echocardiogram. The lower part of the figure shows the electrocardiogram and corresponding ladder diagram (A = atrial; A-V = atrioventricular; V = ventricular conduction). **At top of figure,** A = anterior; I = inferior; P = posterior; S = superior.

analyses limited to the electrocardiogram. Echocardiography can be especially useful in understanding the effects of complex abnormalities such as those resulting from the superimposition of mechanical (for example, alternans) and electrical (for example, Wenckebach periodicity) phenomena during supraventricular arrhythmias. In addition, these studies provide further experimental evidence emphasizing the potential clinical benefits of those cardiac pacing methods that provide optimal A-V sequencing intervals.

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- Address manuscript to Managing Editor, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW: write out superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in *Uniform Requirements for Manuscripts Submitted to Biomedical Journals,* published in *Am Rev Respir Dis* 1979; 119:3–10; *Ann Intern Med* 1979; 90:95–9; *Br Med J* 1979; 1:532–5; and *Lancet* 1979:1:428–30.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals: Table I, II, etc) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying in alphabetical order all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings) Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS, listing *all* authors (if there are 7 or more, list only 3 and add et al.):

INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color

Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

Norpace®
(disopyramide phosphate)

Before prescribing Norpace (disopyramide phosphate), please consult current complete prescribing information, a summary of which follows. ***Indications:*** *For suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.* ***Contraindications:*** *Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.* ***Warnings:*** ***Norpace may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and discontinuation of Norpace considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace with other Type 1 antiarrhythmic agents should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken.*** ***Precautions:*** *Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood* ***Norpace has been reported to stimulate contractions of the pregnant uterus.*** *Use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown. Safety and effectiveness of Norpace in children have not been established.* ***Adverse Reactions:*** *Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported.* ***Dosage and Administration:*** *Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients less than 110 pounds (50 kg) the recommended dosage is 100 mg every six hours. If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg every six hours, with subsequent dosage adjustments made gradually with close monitoring.* ***See current complete prescribing information for dosage recommendations. How Supplied:*** *Capsules containing 100 mg or 150 mg of disopyramide base.*

SEARLE *Searle Laboratories*
Division of Searle Pharmaceuticals Inc.
Box 5110, Chicago, Illinois 60680

The answer is...

Norpace® *in specific ventricular arrhythmias**

(disopyramide phosphate)

Efficacy comparable with quinidine

Proved with Holter recordings in double-blind clinical trials

More compatible with digoxin

Norpace, unlike quinidine, does not cause elevation of serum digoxin levels[2]

Better tolerated than quinidine

One fourth the dropout rate vs quinidine in double-blind clinical trials

Outstanding patient acceptance

- *Easily individualized dosing*
- *Usually well tolerated – even during long-term administration*

As with any antiarrhythmic drug, serious adverse reactions may occur in patients taking Norpace. Please see the facing page for a brief summary of prescribing information.

1980 BOOK NEWS

from the number one name in medical publishing.

Now the definitive work!

Eugene Braunwald's HEART DISEASE A Textbook of Cardiovascular Medicine

Edited by a leading authority in cardiology, this landmark volume provides the most outstanding coverage of cardiovascular medicine available today. Dr. Eugene Braunwald has personally written or co-authored 27 of the 55 chapters. Contributors include 44 of the most eminent names in the field. Over 1,000 figures, 285 tables and 12,700 bibliographic references are provided in this 2,100-page volume. **HEART DISEASE**—now the definitive work.

Edited and with contributions by **Eugene Braunwald,** MD, Hersey Professor of Theory and Practice of Medicine and Head, Department of Medicine at the Peter Bent Brigham Hospital, Harvard Medical School; Physician-in-Chief, Affiliated Hospitals Center, Boston. 1943 pp. 1194 ill. May 1980. Single Vol.: $65.00. **Order #1923-1.** 2-Vol. Set: $75.00. **Order #1924-X.**

Helfant

BELLET'S ESSENTIALS OF CARDIAC ARRYTHMIAS

2nd Edition

This authoritative new edition of Dr. Bellet's classic work clearly defines difficult concepts and demonstrates a sharper awareness of clinical correlations. The chapter on electrophysiology has been completely rewritten and reorganized to include all new research data. Valuable new pharmacology chapters included at the end of the book.

By **Richard H. Helfant,** MD, FACP, FACC, Prof. of Clinical Medicine, Univ. of Pennsylvania School of Medicine, Director, Midatlantic Heart and Vascular Institute, Chief, Division of Cardiology, Presbyterian-University of Pennsylvania Medical Center, Phila., PA. About 430 pp., 210 ill. Ready soon. **Order #4626-3.**

Rapaport

CURRENT CONTROVERSIES IN CARDIOVASCULAR DISEASE

Here are the most pressing, most debated issues in cardiovascular medicine to date, discussed by a renowned expert and a sparkling list of well-known contributors. About 40 topics are covered.

Edited by **Elliot Rapaport,** MD, Prof. of Medicine, Univ. of California, San Francisco; Chief of Cardiology, San Francisco General Hospital, San Francisco, CA. 761 pp. 162 ill. $39.50. April 1980. **Order #7459-3.**

Over 15 years of worldwide clinical experience*†

*Data on file, CIBA Pharmaceutical Company.

†Slow-release potassium chloride tablets should be reserved for patients who cannot tolerate, refuse to take, or have compliance problems with liquid K preparations because of reports of GI ulceration and bleeding with slow-release KCl tablets (total number of GI lesions in both foreign countries and the United States remains less than one per 100,000 patient-years). The incidence of lesions with enteric-coated KCl tablets is 40-50 per 100,000 patient-years.

Please turn page for brief prescribing information.

Experience makes a difference.

Slow-K®

CIBA 165

potassium chloride slow-release tablets 8 mEq

CIBA

potassium chloride slow-release tablets

DESCRIPTION

Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS

BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS

In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS

Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS

Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS

Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE

Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have hac elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

***Dosage:* Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

***How Supplied:* 0.5, 1.0 and 2.0mg tablets.**

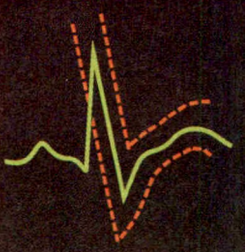
The anxious heart. Since anxiety so often accompanies cardiovascular disease, you may wish to institute adjunctive therapy to help bring this complicating factor under control.

Seven benzodiazepines are now at your disposal. All of them are anxiolytics. One of them—Ativan (lorazepam)—has been specifically evaluated in seven double-blind, controlled studies involving 423 patients (211 on Ativan) and found significantly effective in the relief of anxiety associated with organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

In addition to this outstanding record of clinical usefulness, Ativan offers you a unique pharmacokinetic profile. Unlike older benzodiazepines, it does not generate multiple active metabolites; steady-state serum levels are rapidly achieved and disappear rapidly once you decide to discontinue therapy. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Compatible with cardiotonics, antihypertensives, diuretics, anticoagulants and nonnarcotic analgesics*...usually well tolerated...simple to use on a b.i.d. schedule...a preferred prescription to control anxiety in cardiovascular disease.



*No evidence of any clinically significant interaction between Ativan and any other medication given concomitantly was observed in clinical studies. All benzodiazepines, however, including Ativan, produce added CNS depressant effects when administered with alcohol and other CNS depressants.

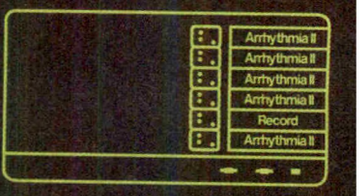
See important information on preceding page.

Ativan® (lorazepam) for Anxiety

No other arrhythmia detection system gives you all t

1

Dramatically reduced false alarms



We start with template matching—the preferred method—to discriminate between the patient's dominant beat and ectopics. But only Arrhythmia II adds two unique features to screen out artifact, ensuring that only qualified ectopic activity triggers alarms or is included in trends: (1) each abnormal beat must appear four times before it's accepted as a "true" ectopic class, and (2) our "over-range" circuitry suspends ECG processing for a minimum of five seconds when it detects excessive noise.

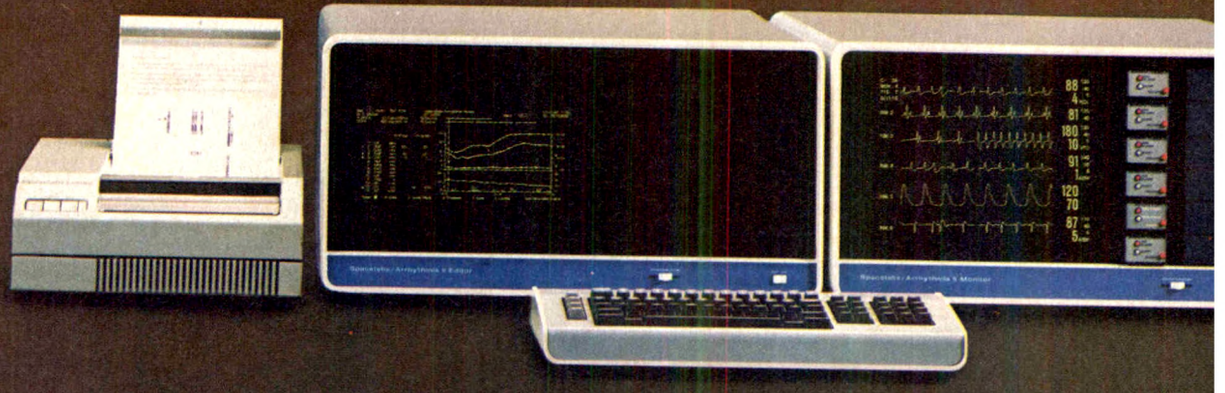
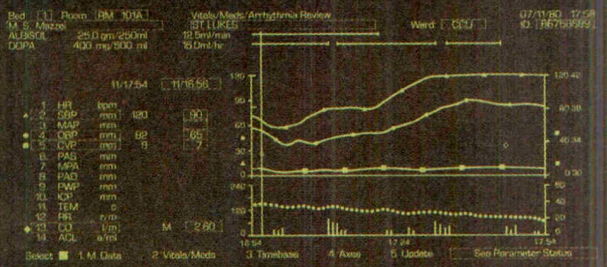
2



More meaningful patient information

Other computerized arrhythmia detection syst may accurately detect and record ectopic acti But we just start there. Only Arrhythmia II allo you to select those ectopics that are particula important for a patient and to include only tho ectopics in trends. You can quickly recall class of ectopics and their frequency over 24 hours And, on the Editor, you can trend a specific cla or combination of classes for 1, 2, 8 or 24 hour without having to edit out each occurrence of unwanted information.



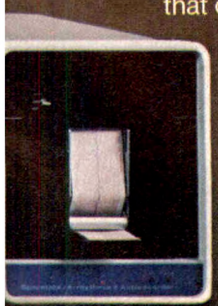
Arrhythmia II

3

See effects of treatment on one screen

Only Arrhythmia II lets you trend medications, ectopics and vital signs on one display, in a concise and easy-to-interpret format. And it provides 24-hour recall so the precise information on ectopics, vital signs and medications is available for any specific time.

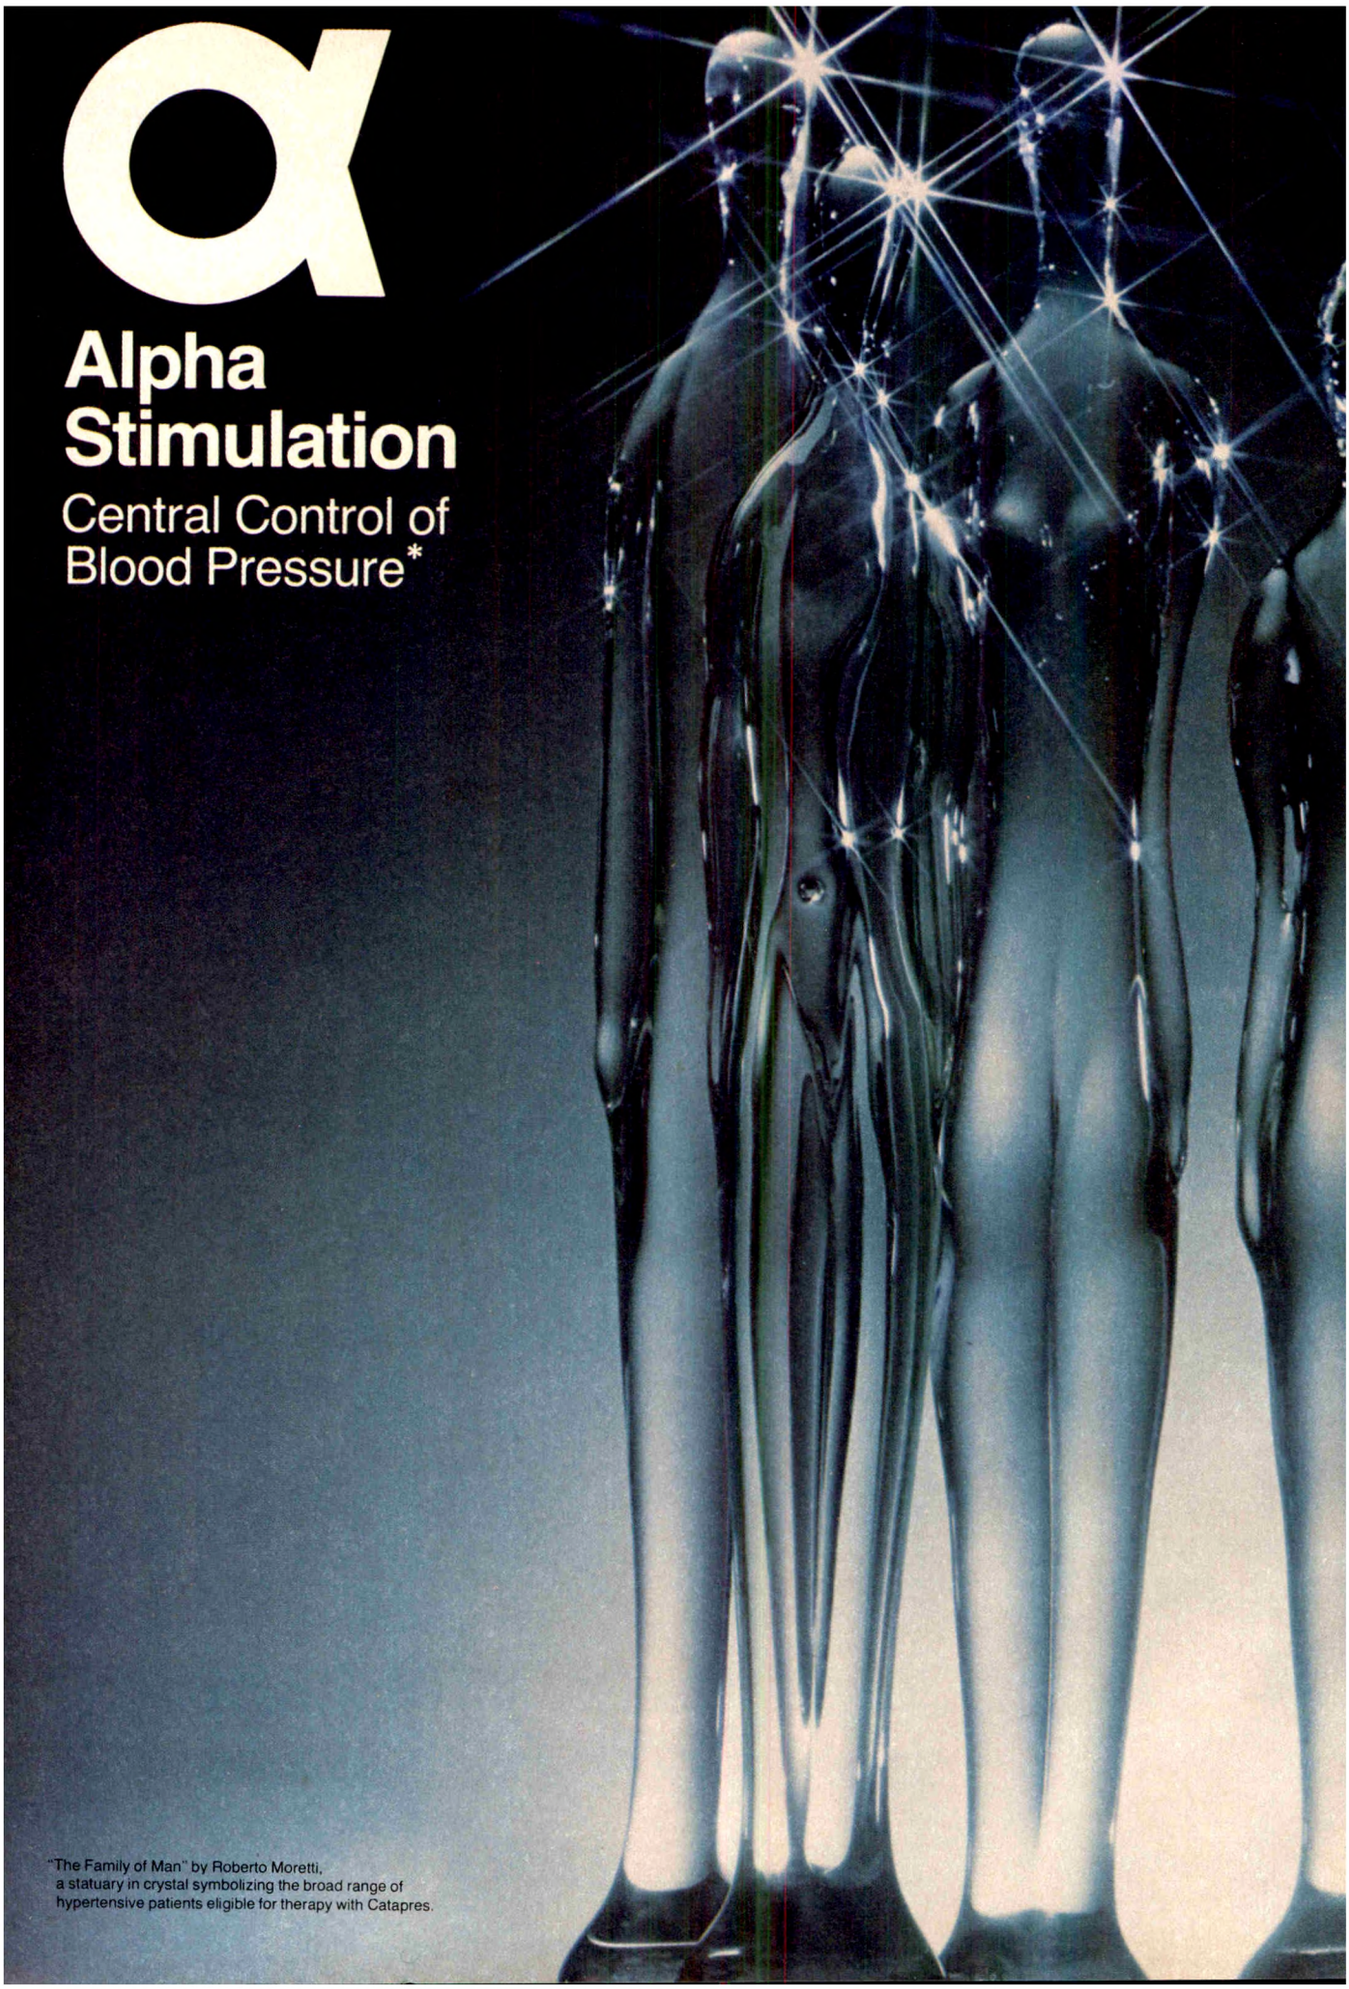
4



Arrhythmia II

A computer for each patient

Hospitals using minicomputer systems have experienced the loss of critical data on all patients connected to the system when the computer malfunctions. But that can't happen with Arrhythmia II, because each patient has his own computer. And any malfunction only affects that one patient. The microprocessor-based cardule can then be replaced in minutes and easily repaired by simply inserting a new circuit board.



We designed Arrhythmia II to solve clinical problems that other arrhythmia systems have not even tried to solve. We feel it represents our care and concern in applying technology to the clinical setting—an approach that has made Spacelabs the fastest growing company in patient monitoring today.

But you don't have to take our word for it. Call us today (213-882-9560, collect) to arrange for an evaluation in *your* hospital. Then we think you'll agree with the growing number of your colleagues who believe that Arrhythmia II is the best system available.

New Dimensions in Monitoring

α
Alpha
Stimulation
Central Control of
Blood Pressure*
"The Family of Man" by Roberto Moretti,
a statuary in crystal symbolizing the broad range of
hypertensive patients eligible for therapy with Catapres.

The Alpha Advantage:

It's for all kinds of hypertensives

- *Unlike beta blockers, Catapres® has no contraindications.*
- *Catapres can be useful even in these patients with:*

Congestive heart failure	Allergic rhinitis
Ventricular hypertrophy	Hepatic disease
Hyperglycemia	Hyperuricemia
Diabetes mellitus	Gouty arthritis
Bronchial asthma	Sulfonamide hypersensitivity

Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

work/play—normal hemodynamic responses to exercise maintained.

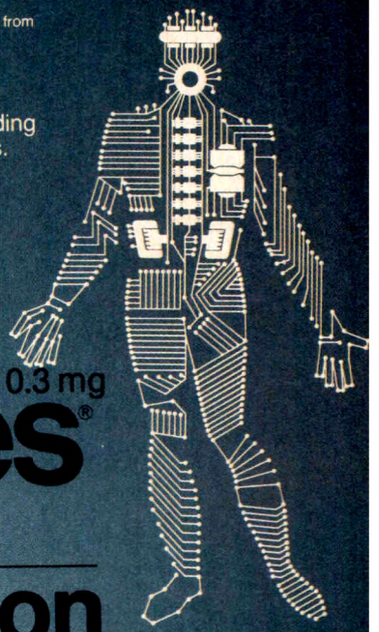
love—low incidence of impotence and/or loss of libido: 2.8% in 1,923 patients studied.[1]

cardiac output—tends to return to control values during long-term therapy.

blood flow—preserved in kidney.

No Single Advantage Determines Drug Choice.

Other factors must include:



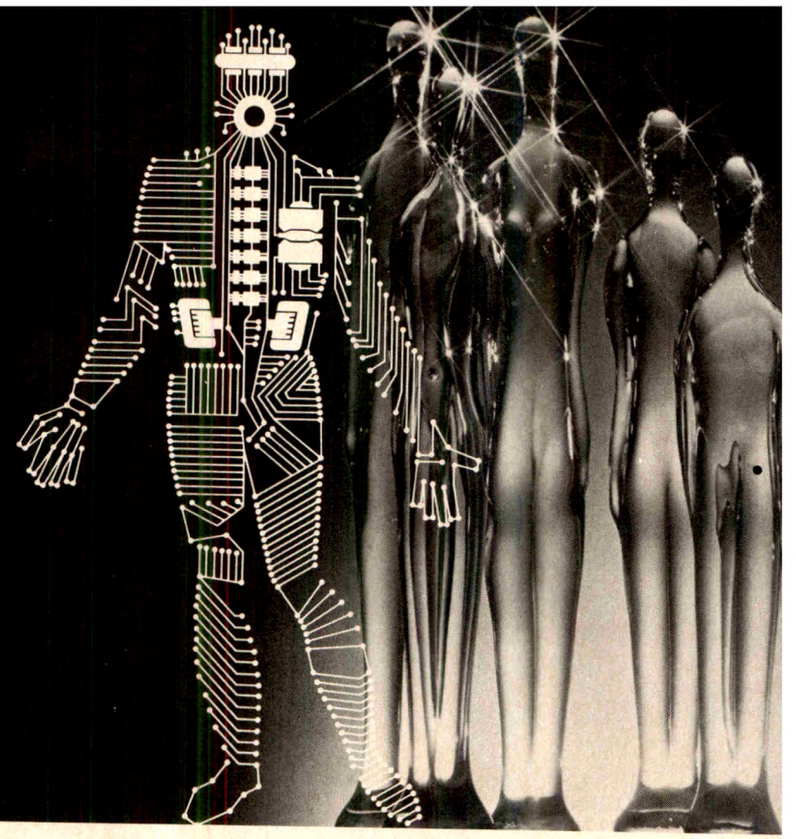
The drug's effectiveness in a given patient, its side effects, warnings, precautions, tolerance, etc. A rational therapeutic choice depends on a careful assessment of all such factors.

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

1. Data on file at Boehringer Ingelheim Ltd.

Please see last page for brief summary, including warnings, precautions, and adverse reactions.

Now available in new 0.3 mg tablets



Tablets of 0.1, 0.2, 0.3 mg

Catapres®
(clonidine HCl)
Hypertension

The Alpha Advantage:

It's for all kinds of hypertensives

Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

Hypertension

- No contraindications.
- Effective in all degrees of hypertension. It is mild to moderate in potency.
- Low incidence of depression, impotence, orthostatic hypotension—no fatal hepatotoxicity.
- Preserves kidney blood flow.

Most common side effects are dry mouth, drowsiness, and sedation which generally tend to diminish with time.

The usual starting dose of Catapres is 0.1 mg at brea fast and 0.1 mg at bedtime. Some patients may bene from a starting dose of 0.1 mg at bedtime.

Usual daily dose range—0.2—0.8 mg

Maximum daily dose—2.4 mg
Doses as high as this have rarely been employed.

For optimal results, the dose of Catapres must be adjusted according to the patient's individual blood pressure response.

Catapres®
(clonidine hydrochloride)
Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 mon longer.

Adverse Reactions: The most common reactions are dry mouth, drowsines sedation. Constipation, dizziness, headache, and fatigue have been rep Generally these effects tend to diminish with continued therapy. The follo reactions have been associated with the drug, some of them rarely. (In instances an exact causal relationship has not been established.) These inc Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalit liver function tests; one report of possible drug-induced hepatitis without ic and hyperbilirubinemia in a patient receiving clonidine hydrochloride, thalidone and papaverine hydrochloride. Weight gain, transient elevation of glucose, or serum creatine phosphokinase: congestive heart failure, Rayn phenomenon; vivid dreams or nightmares, insomnia, other behavioral cha nervousness, restlessness, anxiety and mental depression. Also rash, gioneurotic edema, hives, urticaria, thinning of the hair, pruritus not assoc with a rash, impotence, urinary retention, increased sensitivity to alcohol, dry itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecom weakly positive Coombs' test, asymptomatic electrocardiographic abnorma manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished o sent reflexes and vomiting followed the accidental ingestion of Catapres (clon hydrochloride) by several children from 19 months to 5 years of age. Ga lavage and administration of an analeptic and vasopressor led to complet covery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-mi intervals usually abolishes all effects of Catapres, (clonidine hydrochloride) dosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000. available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

Long-Term Evaluation (12 to 22 Years) of Open Heart Surgery for Tetralogy of Fallot

VALENTIN FUSTER, MD, FACC*
DWIGHT C. McGOON, MD, FACC†
MARGARET A. KENNEDY‡
DONALD G. RITTER, MD, FACC§
JOHN W. KIRKLIN, MD, FACC‖

Rochester, Minnesota
Birmingham, Alabama

Four hundred seventy-five patients underwent repair of tetralogy of Fallot from 1955 to 1964; 396 of these were hospital survivors and were followed up for 12 to 22 years. An excellent late clinical result was maintained by 87 percent of the 396 hospital survivors. A less than excellent result in the remaining 13 percent of hospital survivors was caused by late mortality in 7 percent (sudden death in 3 percent, death due to cardiac causes in 2 percent and death due to noncardiac causes in 2 percent), required reoperation in 4 percent (mainly because of residual ventricular septal defect) and development of symptoms in 2 percent.

Postoperative cardiomegaly (cardiothoracic ratio greater than 0.55) was observed in 60 (25 percent) of 246 patients who had a follow-up chest roentgenogram, and was more common among those who died late or remained symptomatic. Among the few patients with inadequate surgical relief of right ventricular hypertension who did not have transanular patch repair, the hypertension did not tend to decrease progressively, whereas it did decrease in patients who had patch repair. No late sudden deaths were encountered in 20 patients shown to have postoperative right bundle branch block plus left axis deviation (bifascicular block pattern). Pulmonary valve incompetence appeared to have relatively little harmful influence on the late result, causing cardiac disability in 1 percent of the patients and appeared to be the main contributing factor of postoperative cardiomegaly in 13 (5 percent) of the 246 patients who had a follow-up chest roentgenogram. Most late deaths and complications appeared within 2 years of operation, and accelerating deterioration in late results did not occur as the follow-up extended beyond 2 decades.

Intracardiac repair of tetralogy of Fallot has been available for more than 2 decades.[1] During the 1st decade, surgical techniques evolved rapidly—especially with respect to the closure of ventricular septal defect, the outflow tract reconstruction, and the avoidance of surgical damage to the electrical conducting system.[2] After the relative standardization of the surgical technique, interest has been directed to the late results of the operation, especially to the clinical and hemodynamic results and the factors by which late morbidity and mortality might be affected. Among these factors, the most controversial ones are the timing of operation, the indication for outflow patch reconstruction, the identification of patients at risk for late sudden death and the long-term cardiac tolerance of residual significant pulmonary valve incompetence.[3] The present study pursues these controversial factors by analyzing the long-term follow-up of a large series of patients, the earliest operated on for tetralogy of Fallot at the Mayo Clinic.

Methods

Selection of patients: Our definition of tetralogy of Fallot was based on the following qualifying criteria: (1) a large or nonrestrictive ventricular septal defect permitting equalization of pressures between the right and left ventricles, and (2) right ventricular outflow obstruction sufficient to maintain pulmonary arterial systolic pressure no greater than 35 mm Hg; patients whose pulmonary pressure was higher than 35 mm Hg secondary to a previously constructed sys-

From the Division of Cardiovascular Diseases,* Department of Surgery,† Department of Medical Statistics,‡ and Department of Pediatric Cardiology,§ Mayo Clinic and Mayo Foundation, Rochester, Minnesota and from the Department of Surgery,‖ University of Alabama, Birmingham, Alabama. Manuscript received March 3, 1980; revised manuscript received May 6, 1980, accepted May 14, 1980.

TABLE I

Age Distribution of Patients

Age (yr)	Patients	
	n	%
0–1	6	1
2–4	78	16
5–9	184	39
10–19	147	31
20–54	60	13
Total	475	100

temic-pulmonary shunt were included. Luminal continuity between the right ventricle and bilateral pulmonary artery was required; thus, patients were excluded who had congenital or acquired pulmonary atresia or absence of one pulmonary artery. In addition, patients with other major congenital cardiac anomalies were also excluded. Follow-up information was obtained from examinations at the Mayo Clinic, or from responses to letters or telephone calls to the patients or relatives and to the referring physicians; from an original total of 496 patients, the 21 patients for whom complete follow-up data were not obtained (all residing outside the United States) were excluded from the study.

Study patients: Thus, the study group comprised 475 patients, 298 male and 177 female, who underwent intracardiac repair of tetralogy of Fallot at the Mayo Clinic between January 1955 and December 1964. In all 475 patients, the complete follow-up information as defined was obtained in 1976; therefore, all patients were followed up for a minimum of 12 years (or until death, if it occurred in less than 12 years or early postoperatively) and for a maximum of 22 years. The age distribution of the 475 patients in the study group is listed in Table I. Eighty-four patients had primary intracardiac repair within the first 4 years of life and 60 patients between the ages of 20 and 55 years. Before intracardiac repair, 155 patients (33 percent) had had a previous palliative operation: 121 patients had a Blalock-Taussig anastomosis,[4] 27 a Potts-Smith-Gibson anastomosis[5] and 7 a Brock valvulotomy or infundibulectomy, or both.[6] As a measure of residual outflow tract stenosis, intraoperative right ventricular to left ventricular peak pressure ratio was measured after cardiac repair in 438 patients (92 percent).

Postoperative studies: A postoperative cardiac catheterization study was performed in only a selected group of 83 patients; the study was performed 2 weeks postoperatively in about 25 percent of the patients, between 1 and 9 years postoperatively in about 50 percent and between 10 and 21 years postoperatively in the remaining 25 percent. In almost 33 percent of these patients, the catheterization study was performed on a routine follow-up basis; in the remaining 67 percent, it was performed to assess the possibility of residual ventricular septal defect or right-sided outflow obstruction. A total of 246 hospital survivors had follow-up chest roentgenograms that were available to us and were obtained at a median postoperative time of 6 years (range 1 to 22). All hospital survivors had at least two postoperative electrocardiograms that were reviewed by us: one obtained before dismissal from the hospital, and one obtained late postoperatively at a median time of 3 years. The possibility of residual pulmonary valve incompetence was clinically assessed in all hospital survivors before dismissal from the hospital and late postoperatively, either at the follow-up visits at the Mayo Clinic (about half of the patients) or by the local cardiologist. Residual pulmonary valve incompetence was judged significant when there was a loud (grade 2-3/6), low pitched early diastolic decrescendo murmur at the left sternal border, which usually was associated with a thrill.

Results

Symptomatic Results

The overall results of this long-term follow-up study of 475 patients operated on for tetralogy of Fallot are summarized in Table II. An excellent symptomatic result, as judged by the patients' being asymptomatic and having no limitations of usual activities, was obtained in 73 percent of the total group and in 87 percent of the hospital survivors. Thus far, of 150 female patients with an excellent symptomatic result, 27 have had an uneventful pregnancy and 1 had a spontaneous abortion.

A fair symptomatic result, as indicated by mild to moderate physical limitation (see causes in Table II), was obtained in 2 percent of patients. Nineteen patients (4 percent of the total group and 5 percent of hospital survivors) underwent reoperation; of these 19 patients, 4 died at the time of reoperation (21 percent mortality rate) and 1 died late postoperatively. The hospital mortality rate in those early years of open heart surgery was 16 percent. The late mortality rate was 6 percent.

The actuarial curves of survival and survival with an excellent result are shown in Figure 1. These demonstrate that most late problems appear within 2 years of operation, but that thereafter the slope of the line is nearly horizontal and comparable with that of the

* On selected catheterization, 11 patients have ventricular septal defect with less than 1.5:1 shunt; 5 patients have persistent outflow gradient with a right to left ventricular peak pressure ratio higher than 0.65. † Three patients probably have primary myocardial dysfunction as judged from the persistent cardiomegaly that was already present preoperatively (no prior anastomotic operation) and lack of postoperative evidence of pulmonary valve incompetence; two patients have significant pulmonary valve incompetence; four have a permanent pacemaker and one patient has recurrent supraventricular tachycardia. ‡ Four patients died at time of reoperation and one patient died 5 years after reoperation.

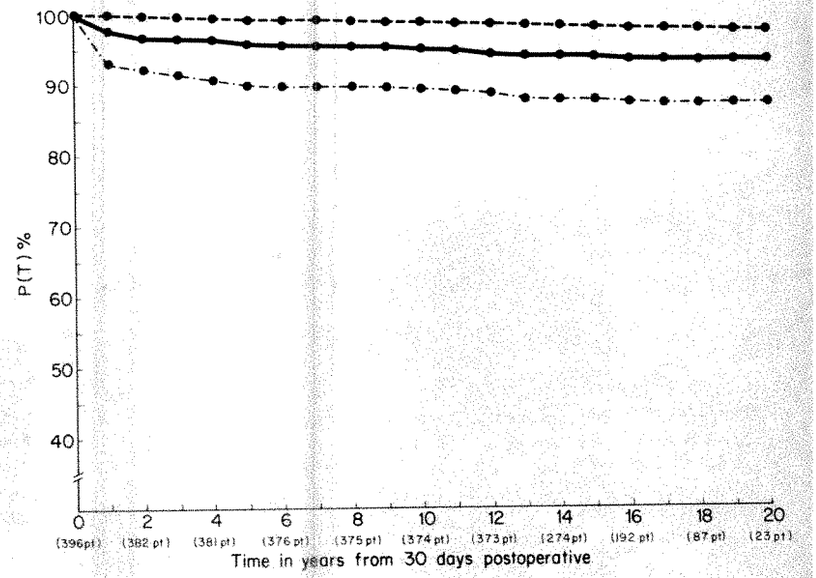

FIGURE 1. Probability of deterioration [P(T)] in operative survivors plotted against time in years. Time of deterioration is defined as postoperative year in which late death occurred (**middle curve**) or in which death, reoperation or symptoms occurred (**bottom curve**). The **top curve** represents the control expected survivorship on the basis of age and sex distribution, under the death rates of the Minnesota 1970 white population life table. The number of patients (pt) seen at each follow-up interval is denoted within parentheses.

control age- and sex-matched general population. Late mortality and reoperation were the two major reasons for the decrease in excellent results during the first 2 postoperative years.

Mortality and Reoperation

Contributing factors and causes of early mortality (Table II, Fig. 2): Improvement in surgical results occurred through the years of this experience. Hospital or early mortality after total correction was importantly influenced by the age of the patients at the time of operation (Fig. 3); thus, the hospital mortality in patients operated on before age 5 years was significantly greater than that in older patients ($p < 0.01$). Intraoperatively, the right to left ventricular pressure ratio (RV/LV) after repair was significantly higher for the group that died in the early postoperative period (mean 0.638 versus 0.503; $p < 0.001$). The Armelage test for linear trend[7] in the individual patient revealed that early operative mortality was proportionally related to an RV/LV ratio of 0.65 or greater and was not influenced by a ratio of less than 0.65 (Fig. 4). In that early experience, there was evidence of a higher early mortality rate among the patients who had a transanular patch for the relief of outflow obstruction ($p < 0.01$) (Table III). This finding could be partly related to: (1) the younger age of these patients (under age 5 years) at the time of operation ($p < 0.05$), and (2) a higher intraoperative RV/LV pressure ratio (0.65 or greater) or insufficient relief of pulmonary stenosis after the repair ($p < 0.05$). The presence and type of prior palliative anastomotic operation were not associated with early death (Fig. 5). The specific causes of early mortality are expressed in Table IV.

Contributing factors and causes of late mortality: Late mortality was not influenced by the age of the patient at the time of operation (Fig. 3), by the intra-

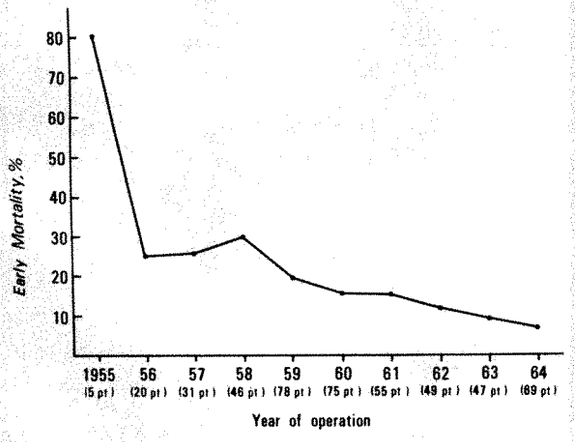

FIGURE 2. Hospital or early mortality rates (death within 30 days of operation) in 475 patients subjected to intracardiac repair for tetralogy of Fallot between 1955 and 1964, with a long-term follow-up of 12 to 22 years. Observe the improvement in surgical results through the years. The number of patients (pt) operated on each year is denoted within parentheses.

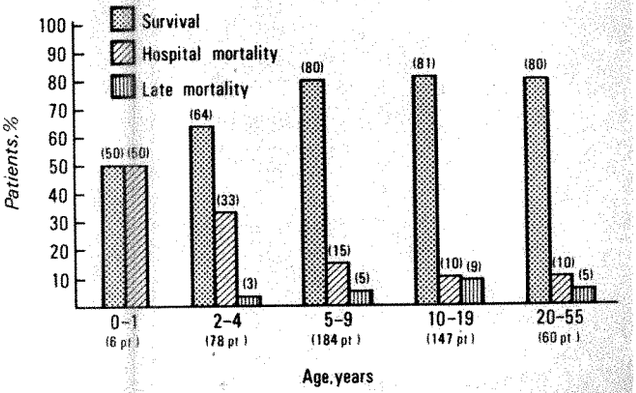

FIGURE 3. Relation between age of patient (pt) at time of intracardiac repair and survivorship, hospital mortality and late mortality. The number of patients within each age group is shown at bottom in parentheses.

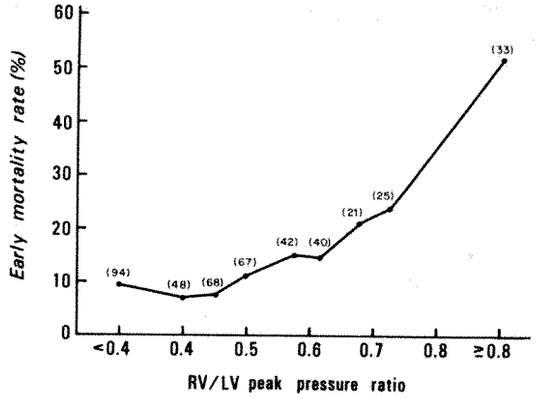

FIGURE 4. Relation between intraoperative right ventricular to left ventricular (RV/LV) peak pressure ratio and early mortality. Observe that ratios of 0.65 or greater were proportionately associated with mortality. The number of patients with each intraoperative ratio is denoted within parentheses.

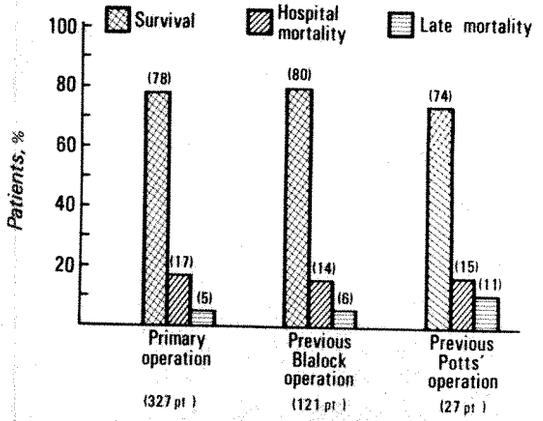

FIGURE 5. Relation between primary intracardiac operation or previous specific palliative operations followed by intracardiac repair and survivorship, hospital mortality, and late mortality. The number of patients in each surgical group is shown at bottom in parentheses.

operative RV/LV pressure ratio, or by the presence and type of prior anastomotic operation (Fig. 5); although there was a trend toward a higher late mortality rate in patients with a higher intraoperative RV/LV pressure ratio and in patients with a prior Potts' anastomosis, it did not reach statistical significance ($p = 0.14$). The specific causes of the 27 late deaths and the postoperative time of their occurrence are listed in Table V. Fifteen (71 percent) of the 21 deaths due to cardiac causes occurred within the first 2 postoperative years.

Sudden death (Table VI), without previous evidence of cardiac symptoms, occurred in 12 patients (3 percent). A possible contributing factor in four of the sudden deaths was the presence of a significant residual ventricular septal defect that in three patients was associated with significant cardiomegaly (cardiothoracic ratio greater than 0.60): In two patients a large defect was demonstrated at autopsy, in one patient the defect had been demonstrated 9 years before at cardiac catheterization (1.4:1 shunt), and in one the defect had been suspected clinically and the patient died before catheterization. One of these patients with a residual ventricular septal defect had well documented ventricular tachycardia before death; two of the other three patients had transient junctional rhythm early postoperatively but no detectable arrhythmias on routine follow-up study. In four patients the exact cause of death could not be identified clinically or at autopsy, although three of the four had significant cardiomegaly (cardiothoracic ratio greater than 0.60). One of these patients died with well documented ventricular fibrillation and another had had transient junctional rhythm early postoperatively but no detectable heart block or arrhythmias on routine follow-up study. In three patients, late sudden death was related to the operative complication of complete heart block when pacemakers were only in the initial stages of development; none of the other patients with late sudden death had preceding evidence of complete heart block or bifascicular block (right bundle branch block and left axis deviation).

Right ventricular outflow abnormalities were the cause of death in seven patients (1.5 percent) (Table V). Three patients died during reoperation for an aneurysm of the outflow patch. Possible contributing factors to the formation of the aneurysm were the Ivalon® type of patch used in the initial operation of all three patients and the higher than 0.65 RV/LV pressure ratio present after repair in two of the three. Two patients died as a result of the right ventricular outflow obstruction with right ventricular failure. In one of these patients the significant residual obstruction was known to be present at the initial operation, but for technical reasons an outflow patch could not be inserted; in the other patient no significant residual obstruction was detected at operation but was found at cardiac cathe-

terization 9 years later. Finally, one patient died as a result of severe pulmonary valve incompetence and one as a result of bacterial endocarditis.

Contributing factors leading to reoperation: Nineteen patients (4 percent) required reoperation, and 14 of them are alive. In 14 of the 19 reoperation was performed because of a residual or recurrent ventricular septal defect. One of these patients died at the time of reoperation and another died 5 months postoperatively. Sixteen other patients with a residual or recurrent ventricular septal defect, all with less than a 1.5:1 shunt, did not undergo reoperation. Between 1955 and 1959, the use of an Ivalon patch for primary closure of the ventricular septal defect, in contrast to the use of direct suture repair or the later Teflon® patch, appeared to contribute significantly to the incidence of residual or recurrent defect ($p < 0.01$).

Five patients were reoperated on as a result of a right-sided outflow abnormality. Three of these patients died at the time of reoperation. The other two patients are alive; in both patients the RV/LV pressure ratio was already higher than 0.65 after the initial operation.

Specific Clinical Features of the Hospital Survivors

Postoperative heart size: Among the 246 hospital survivors who had a follow-up chest roentgenogram, cardiac enlargement, defined as a cardiothoracic ratio higher than 0.55, was observed in 60 (25 percent). However, this specifically occurred in 5 (56 percent) of the 9 asymptomatic patients and in 13 (62 percent) of the 21 who died late of cardiac causes. Of eight patients with late sudden unexpected death whose data were available, six had significant cardiomegaly: (related to a significant ventricular septal defect in three, caused by persistence of preoperative cardiomegaly in two and without apparent cause in one).

The exact contributing factors accounting for the postoperative increase in cardiac size were difficult to define because postoperative cardiac catheterization studies performed to search for residual intracardiac lesions were performed only in selected patients. Nevertheless, the apparent most important contributing factors accounting for the postoperative increase in heart size (Table VII) were preoperative cardiomegaly persisting postoperatively (about 33 percent of these patients), significant residual pulmonary valve incompetence (about 25 percent) and a significant residual ventricular septal defect (about 17 percent). A patch across the pulmonary anulus was present in 28 (46 percent) of the 60 patients with postoperative cardiomegaly and in only 50 (27 percent) of the 186 patients without postoperative cardiomegaly; this greater incidence of cardiomegaly in patients with a transanular patch was probably in part related to the residual significant pulmonary valve incompetence observed in some of these patients (11 of 28).

Pulmonary valve incompetence: All patients, after insertion of an outflow patch across the pulmonary valve anulus, have some degree of pulmonary valve incompetence. Also, some patients who undergo pulmonary valvotomy later manifest pulmonary incompetence. In our study, significant pulmonary valve incompetence contributed to some type of disability in only 3 (1 percent) of the 396 hospital survivors (1 patient who died late and 2 symptomatic patients). However, significant pulmonary valve incompetence appeared to be the most likely contributing factor for the postoperative increase in heart size in 13 (5 percent) of the 246 hospital survivors who had follow-up chest roentgenograms.

Residual pulmonary stenosis: Thirty-three of the surviving patients who had follow-up cardiac catheterization at least 1 year (range 1 to 21 years) postop-

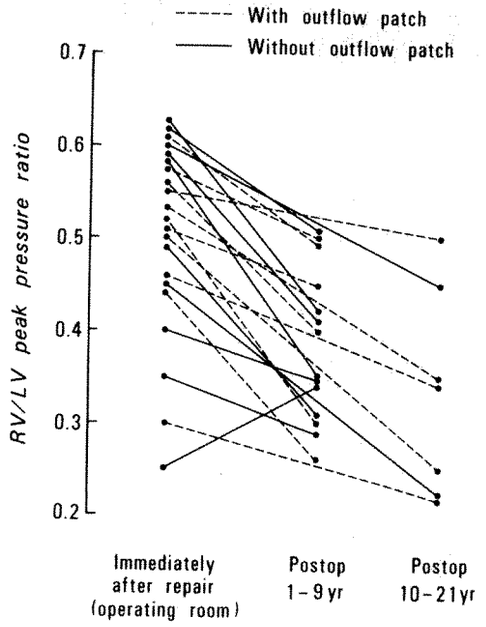

FIGURE 6. Right ventricular to left ventricular (RV/LV) peak pressure ratio in 21 patients whose ratio was less than 0.65 immediately after repair (operating room) and who underwent a second hemodynamic study between 1 and 21 years of the follow-up study (Postop). With one exception, the pressure ratio was lower in the second hemodynamic study in all patients.

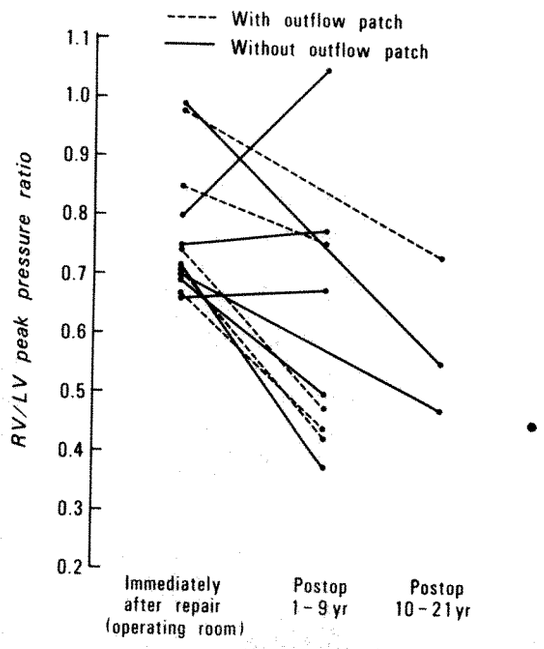

FIGURE 7. Right ventricular to left ventricular (RV/LV) peak pressure ratio in 12 patients whose ratio was more than 0.65 immediately after repair (operating room) and who underwent a second hemodynamic study between 1 and 21 years of follow-up (postop). In three of the seven patients without an outflow patch the pressure ratio did not decrease.

eratively and who showed no residual ventricular septal defect were evaluated for right ventricular outflow obstruction. The right ventricular to left ventricular (RV/LV) pressure ratio obtained at catheterization was compared with ratios obtained in the operating room after cardiac repair was completed (Fig. 6). In 21 patients with an intraoperative RV/LV pressure ratio of less than 0.65, there was a significant tendency for this ratio to decrease with the years of follow-up in both the group with and the group without an outflow patch ($p < 0.01$); in fact, none of these patients with an intraoperative pressure ratio of less than 0.65 had a ratio greater than 0.52 late postoperatively. In five patients with an outflow patch and an intraoperative RV/LV pressure ratio 0.65 or greater (Fig. 7), there was a significant tendency for this ratio to decrease with the years of follow-up ($p < 0.01$), although in two patients the ratio was still greater than 0.50. There was no significant average decrease in the elevated RV/LV pressure ratio in the seven patients without an outflow patch, although all of them were asymptomatic. An intraoperative post-repair RV/LV pressure ratio of 0.65 or greater was observed in 63 (16 percent) of the 396 hospital survivors, and specifically, in 6 (29 percent) of 21 who died late of cardiac causes and in 2 (25 percent) of the 8 whose death was sudden and unexpected ($p = 0.33$).

Electrocardiographic conduction abnormalities: A complete right bundle branch block pattern was found in 337 (85 percent) of the 396 hospital survivors. Twenty (7 percent) of the 337 patients had additional left axis deviation (bifascicular block pattern); as discussed earlier, none of these patients had late sudden death, but one had transient complete atrioventricular (A-V) block at the time of operation. An incomplete right bundle branch block pattern was found in 23 (6 percent) of the 396 patients.

Permanent complete A-V block was observed in 7 (2 percent) of the 396 patients; 3 of these patients had late sudden death and, as discussed, this occurred when pacemakers were only in the initial stages of development. The four other patients have a permanent pacemaker, implanted in two at the time of operation and in the other 2 years later when permanent complete A-V block developed. Transient complete A-V block at the time of operation occurred in 14 (3.5 percent) of the 396 patients; permanent A-V block developed years later in only 2 of these 14 patients, and as mentioned, both required a permanent pacemaker.

Discussion

This review, which is primarily a study of the clinical status of patients after repair of tetralogy of Fallot, is unique because the study group consists of one of the largest and earliest surgical series. It involves patients operated on during the first 10 years that this operation was available, and provides a follow-up review of 12 to 22 years. Aside from the higher hospital mortality rate encountered in this earliest experience, the results compare favorably with that of a later experience at this same institution involving patients operated on after the early years of rapid evolution of operative techniques.[8] Thus, 12 to 22 years following the repair, 87 percent of the hospital survivors had an excellent result, as judged by their asymptomatic status and freedom

from limitations on their usual daily activities. When contrasted with the poor life expectancy without operation,[9] the good operative result is most gratifying, despite a mild to moderate increase in heart size in some patients and despite reports that a significant number of patients after repair of tetralogy of Fallot show a good symptomatic result but have abnormal hemodynamics[10] or reduced cardiac output and heart rate response to exercise.[11-14] Because in our hospital survivors a follow-up cardiac catheterization was performed in a selected group of only 83 patients, an accurate evaluation of the postoperative hemodynamics and of the incidence of residual structural lesions could not be obtained for the total study group.

• **Hospital mortality:** The principal detractor from an excellent result was the hospital mortality rate, which was 26 percent in the period from 1955 to 1959 and has steadily decreased throughout the later years of this study. The increased mortality that occurred between 1955 and 1959 was partly due to impaired ability to avoid the production of permanent complete heart block.[15] The significantly greater hospital mortality in infants and young children than in older patients may not be relevant to the present time,[16-20] with its improved operative and postoperative methods, but it does suggest that the margin for mismanagement may be much narrower in the younger age group. Although in this early experience patients with a transanular patch had a significantly greater hospital mortality, this finding has not been documented in our most recent experience.[8]

Late mortality: Although less common than hospital mortality in this early experience, the occurrence of late death is of some concern currently, because it appeared most commonly as a sudden event and within the first 2 postoperative years. Continued study of this problem is clearly important in an effort to identify causative factors or to develop methods to minimize its hazard. Thus, sudden death occurred in 12 patients. Four of these deaths would be rare today because three were related to A-V heart block when pacemakers were only in the earliest stages of development and one was secondary to pulmonary hypertension as a result of a previous Potts' anastomosis. Of interest is the sudden death of four patients with significant size residual or recurrent ventricular septal defect and significant cardiomegaly in three of them. One of these patients had well documented ventricular tachycardia before death. Furthermore, of the remaining four patients in whom an anatomic cause of death could not be identified, three had significant cardiomegaly and one of them died with well documented ventricular fibrillation. It is then possible, as suggested by other reports,[21-23] that most sudden deaths were related to ventricular arrhythmias. Our data also suggest that in many of these patients myocardial dysfunction, as judged from significant cardiomegaly, may trigger the arrhythmia. These observations raise the possibility that follow-up cardiac catheterization to rule out a significant residual structural lesion should be performed in patients after repair of tetrology of Fallot, particularly in those with significant cardiomegaly. Patients with primary myocardial dysfunction might be subjected to a treadmill stress test and 24-hour Holter electrocardiographic monitoring to identify those who might benefit from antiarrhythmic therapy. However, the impact on mortality would be minimal because sudden, unexplained death, presumably related to cardiac arrhythmia, occurred in only four of our patients (0.8 percent), and a similar low incidence rate (0.9 percent) was also documented in our more recent patients operated on from 1965 through 1970.[8]

Not one of the patients who died suddenly had demonstrated bifascicular block. A similar lack of relation between bifascicular block and late sudden death was also apparent in the group operated on from 1965 through 1970.[8] Thus, contrary to the views of other investigators,[24-27] our data and those of others[28,29] do not justify a prognostic electrophysiologic study of the conduction system in postoperative patients with bifascicular block.

Other causes for late death or reoperation required because of incomplete closure of ventricular septal defect or insufficient relief of pulmonary stenosis are related to surgical techniques. Thus, they have been largely avoided more recently by abandonment of closure of ventricular septal defect with improper patches (Ivalon), and by willingness to use outflow patch gussets in order to avoid high residual gradients. Similarly, these technical improvements minimize the current probability that reoperation will be required.

Role of residual pulmonary stenosis versus pulmonary incompetence: The question whether patch graft reconstruction of the outflow tract is advisable in borderline situations has been dealt with extensively.[22,30-32] Over the years, the difference of opinion had focused on the ill effects of residual pulmonary stenosis versus insufficiency. The present data suggest that the immediate post-repair right to left ventricular pressure ratio is usually higher than it will be as the years of follow-up elapse, whether or not a patch reconstruction is used. However, in patients in whom the immediate post-repair pressure ratio is highest (0.65 or greater), there is a risk, for those in whom an outflow patch is not used, that the pressure ratio will not decrease with time (three of our seven patients), that reoperation will be required (two other patients) or that even death might ensue (one other patient). Moreover, as documented by others,[33] the outflow gradients can increase markedly during exercise.

The insertion of an outflow patch across the pulmonary valve anulus always results in some degree of pulmonary valve incompetence. However, recent hemodynamic data[34,35] indicate that the majority of patients tolerate this lesion well for many years and that their response to exercise remains adequate if there is no significant residual obstruction. Indeed, in our long-term study, pulmonary incompetence has contributed to only 1 late death, to the symptoms of 2 patients, and probably, to the mild increase in heart size of 13 of the 246 patients who had follow-up chest roentgenograms. For these reasons, thus far we do not favor use of more recently introduced techniques of insertion of substitute pulmonary valves or outflow tract conduits, except in patients with impaired pulmonary arterial runoff

caused by peripheral stenosis, vascular obstructive disease, single pulmonary artery or agenesis of pulmonary valve with aneurysm of the central pulmonary arteries.

Role of residual anatomic and functional abnormality: Of particular concern with respect to the late result of corrective operation for patients with tetralogy of Fallot is the usual failure of correction to restore the heart to normalcy. Residual anatomic and functional abnormality exists, particularly at the right ventricular outflow tract level, and to some extent the right ventricular myocardium may be permanently altered. Thus, because asymptomatic patients may have a poor hemodynamic result, their lack of symptoms must be viewed with some caution. However, if these residual alterations were to exert a significant, time-related adverse effect on the late result of operation, a downturn in the actuarial survival curves should occur by 20 years after operation. The absence of such a downturn in our study (Fig. 1) is highly gratifying.

Acknowledgment

We greatly appreciate the valuable help of Lila R. Elveback, PhD and Kim Denise Jones (Department of Medical Statistics and Epidemiology). We also express our thanks for the excellent secretarial assistance of Darlene Albrecht.

Cardiac Malformations in the Velocardiofacial Syndrome

DENNISON YOUNG, MD, FACC
ROBERT J. SHPRINTZEN, PhD
ROSALIE B. GOLDBERG, MS

Bronx, New York

A similar pattern of congenital anomalies found in 27 children, 9 male and 18 female, aged 2 weeks to 17 years, allows the conclusion that they represent a newly recognized malformation syndrome. All patients had velopharyngeal insufficiency, a submucous or overt cleft of the secondary palate and learning disabilities. A similar facies, characterized by a long vertical face, a large fleshy nose with broad nasal bridge, flattened malar region, narrow palpebral fissures and deep overbite with retruded mandible, was usually present. Other noncardiac anomalies also occurred frequently. Twenty-three (85 percent) had congenital cardiovascular malformations whose occurrence as single or combined lesions far exceeded the expected incidence in children with congenital heart disease. A ventricular septal defect was present in 15, tetralogy of Fallot in 5. Prolapse of the right aortic cusp was present in two patients with a ventricular septal defect, and aortic valve disease with insufficiency in one patient with tetralogy. The aortic arch was right-sided in 12 patients, in conjunction with a ventricular septal defect in 5, in association with tetralogy of Fallot in 4 and in the absence of associated cardiac disease in 3. The right aortic arch descended on the right in 10 patients; in 2 with a ventricular septal defect it crossed retroesophageally to descend on the left, and in one of these it presented as the "third aortic arch syndrome." Aberrant origin of the left subclavian artery was present in five patients with a right aortic arch. A patent ductus arteriosus had caused congestive heart failure in infancy in one patient with a small ventricular septal defect; three others with a ventricular defect had additional clinically minor anomalies. Two children were brother and sister. Their mother and the mothers of two other children showed evidence of the same syndrome, suggesting the possibility of autosomal dominant or X chromosome-linked dominant transmission.

In an earlier report[1] we described 12 children with a pattern of similar malformations believed to represent a newly recognized congenital malformation syndrome. Although other manifestations with varying frequency were noted, most consistently present were overt or submucous clefts of the secondary palate, typical facies, learning disabilities and ventricular septal defect; hence, the designation velocardiofacial syndrome. The occurrence in all patients of velopharyngeal insufficiency, generally reflecting poor motion in the lateral pharyngeal walls, necessitated specific surgical correction.

Twenty-seven children with this syndrome have now been evaluated in this center. Twenty-three have shown cardiovascular anomalies. This report details our observations in these 23 patients and presents an unusual conformity of cardiac involvement.

Methods

Patients: Of the 27 children 9 were male and 18 female. Their ages on initial referral ranged from 2 months to 17 years. Twenty-two were referred because of hypernasal speech, usually considered of unknown origin. Two were neonates referred because of clefts of the velum and suspected Robin malformation complex.[2] Three were initially seen for cardiac evaluation, at which time the diagnosis of velocardiofacial syndrome was made. Cardiovascular disease had been recognized or suspected in 16 before their coming under our care.

From the Center for Craniofacial Disorders and the Department of Pediatrics, Division of Cardiology, Montefiore Hospital and Medical Center, Albert Einstein College of Medicine, Bronx, New York. Manuscript received January 1, 1980; revised manuscript received March 18, 1980, accepted April 18, 1980.

Address for reprints: Dennison Young, MD, Department of Pediatrics, Montefiore Hospital and Medical Center, 111 East 210 Street, Bronx, New York 10467.

Detailed histories for possible teratogenic or environmental influences or familial genetic factors were obtained on all patients. Chromosomal studies were obtained in four patients.

Diagnostic procedures: The cardiac diagnosis, established by physical examination, electrocardiogram and roentgenograms of the chest in all, was confirmed by cardiac catheterization and angiocardiography in 17 and at cardiac surgery in 9. Thirteen had undergone previous diagnostic cardiovascular study elsewhere. Repeat studies were obtained in one of these and initial cardiac catheterization was performed in four patients in our institution. Seven had undergone previous cardiac surgery elsewhere and two patients were operated on in our institution. All catheterization data, angiocardiograms and operative reports were reviewed.

Results

Noncardiac Malformations

The noncardiac malformations present are listed in Table I. Most frequent were hypernasal speech with overt or submucous clefts of the secondary palate, similar facies and specific learning disabilities, usually involving the ability to form abstractions, mathematical ability and visual-motor capacity. Only 12 patients were significantly retarded. All of the intellectually impaired patients were in the educable range with the exception of one trainably retarded patient.

The most striking feature of these patients was the similar facies (*Fig. 1*). This was characterized by a large, fleshy nose with a broad nasal bridge, flattened malar region, narrow palpebral fissures, deep overbite with a class II malocclusion and retruded mandible, abundant scalp hair and a vertically long face.

Chromosomal studies were normal in all patients whose karotypes were obtained. Three instances of familial occurrence of the syndrome were recognized. The mother of one girl with a ventricular septal defect showed a similar facies, a large U-shaped palatal defect with hypernasal speech, a retruded mandible and learning disabilities, but no cardiovascular abnormalities. The mother of another girl with a ventricular septal defect also had a similar facies with microcephaly and a submucous palatal cleft. Two patients with tetralogy of Fallot were brother and sister. Their mother was retarded, showed a palatal cleft, typical facies and a normal heart and aorta.

Four unaffected mothers had received progestational agents during the early first trimester of pregnancy. In addition, one mother was an operating room nurse who had been exposed to anesthetic gases during pregnancy.

TABLE I

Velocardiofacial Syndrome: Noncardiac Malformations in 27 Patients

	n	%
Submucous cleft of secondary palate	19	70
Overt cleft of secondary palate	8	30
Learning disabilities	27	100
Hypotonia in infancy	23	85
Narrow palpebral fissures	21	78
Retruded mandible	19	70
Malar flatness	19	70
Auricular anomalies	19	70
Prominent nose	18	67
Slender hypotonic hands	14	52
Microcephaly	12	44
Mental retardation	12	44
Small stature	11	41
Inguinal hernia	5	27
Vertebral anomalies	3	11

Cardiovascular Malformations

Congenital cardiovascular malformations were demonstrated in 23 (85 percent) of the 27 patients (Table II).

Ventricular septal defect: A ventricular septal defect was present in 15 patients (65 percent). Ten had a normal left aortic arch and five (33 percent) a right aortic arch. One patient, first seen at age 6 years with an isolated right-sided aorta and mild left ventricular enlargement in the chest roentgenogram, had a history of a heart murmur in infancy. He may have had spontaneous closure of a ventricular septal defect at an earlier age.

Two of the five patients with a ventricular septal defect and right aortic arch also showed prolapse of the right aortic cusp. In one, aortic insufficiency was not clinically apparent but prolapse was demonstrated

		"Third aortic arch syndrome"	1
Tetralogy of Fallot			
Left aortic arch	1	Left superior vena cava	1
Right aortic arch (not retroesophageal)	4	Aberrant left subclavian artery with left patent ductus arteriosus; aortic insufficiency	1
Total	27		14

FIGURE 1. Characteristic facies in children with the velocardiofacial syndrome. Note the large fleshy nose with a broad nasal bridge, flattened malar region, vertical long face, retruded mandible, auricular malformation and abundant hair. The patient in the panels **at bottom** demonstrates narrow palpebral fissures with a downward obliquity.

angiographically. In the other patient aortic insufficiency was marked.

Cardiac catheterization was performed in 11 patients with a ventricular septal defect. The ratio of pulmonary to systemic blood flow ranged from 1.4 to 2.6. The shunt was demonstrable only on angiocardiography in three. Pulmonary vascular resistance was normal in all.

Tetralogy of Fallot: Five patients (21 percent) presented with tetralogy of Fallot, and four (80 percent) of these had a right aortic arch. One probably originally had a large ventricular septal defect that was altered to tetralogy as a result of progressive infundibular hypertrophy.

Right aortic arch: A right-sided aortic arch was present in 12 patients (52 percent). Four of the 12 had no evidence of heart disease. In three of the four the arch was anterior and to the right of the esophagus, descending on the right with no retroesophageal component. In the fourth patient the angiogram revealed the branches of the aorta to be the left common carotid, the right common carotid and the right subclavian arteries, with the left subclavian artery arising as the fourth branch from the left dorsal aspect of the upper descending aorta, crossing behind the esophagus and indenting its posterior wall.

Of the five patients with ventricular septal defect and a right-sided aortic arch, three manifested an aorta that descended on the right and had no retroesophageal component. One of these three also had an aberrant left subclavian artery crossing the mid line behind the esophagus.

The remaining two manifested a right aortic arch with a retroesophageal component and descent of the aorta on the left. One showed a cervical position of the right-sided aortic arch ("third aortic arch syndrome") from which the first three great vessels arose, respectively, as the left common carotid, the right common carotid and the right subclavian artery, with the left subclavian artery arising as the fourth brachiocephalic vessel from a diverticulum at the junction of the right aortic arch and upper descending aorta. In the second patient, who also had a prolapsed right aortic cusp, the left subclavian artery also arose aberrantly as the fourth branch of the aorta.

Four patients with the tetralogy of Fallot had a right aortic arch and descending aorta. Three showed mirror-image branching of the brachiocephalic vessels. However, one had an aberrant left subclavian artery with a patent ductus arteriosus connecting it to the left pulmonary artery to form a vascular ring.

Other cardiovascular abnormalities: Most additional cardiac malformations were of no physiologic significance (Table II). One child with a ventricular septal defect who had had congestive heart failure in infancy showed mild valvular and infundibular pulmonary stenosis with a right ventricular-pulmonary artery gradient of 25 mm Hg at age 5 years. Another with a small ventricular septal defect had had congestive failure in infancy primarily because of a large patent ductus arteriosus. The patient with tetralogy, right aortic arch and vascular ring also had a thickened aortic valve with aortic insufficiency.

Bacterial endocarditis had occurred in one patient. One patient with a right aortic arch and no evidence of structural heart disease showed varying nodal rhythm and atrioventricular dissociation; these abnormalities posed no problem during her palatal surgery.

Discussion

Incidence of cardiovascular malformations associated with facial clefting: Cardiac lesions in association with facial clefting were considered relatively rare by McKeown and Record.[3] Among 55,539 live births, there were only 5 such patients, all of whom died in the 1st month of life. Shah et al.[4] reported a 1.3 percent incidence rate of congenital heart defects in 150 living patients with facial clefts. Of these 10 patients, 3 had an isolated ventricular septal defect and 2 a ventricular septal defect in conjunction with other cardiac defects. None had a right aortic arch.

In our Center for Craniofacial Disorders, of 275 patients with an isolated cleft palate, not part of other malformation syndromes, 7 children (2.5 percent) have shown evidence of congenital heart disease: 3 with coarctation of the aorta (including 1 with ventricular septal defect and patent ductus arteriosus) and 1 each with secundum atrial septal defect, aortic stenosis, pulmonary stenosis and patent ductus arteriosus.

Incidence of cardiovascular malformations in velocardiofacial syndrome: The incidence of cardiovascular malformations, either as single or combined lesions in this group of patients with the velocardiofacial syndrome, far exceeds the expected incidence in children with congenital heart disease. Among 56,109 births recorded by Mitchell et al.,[5] 457 infants had congenital heart disease. A ventricular septal defect was present in 29 percent, tetralogy of Fallot in 3.5 percent and a right aortic arch and patent ductus arteriosus in two infants. At a median age of 3 years in those with congenital heart disease, the incidence rate was 40 percent for ventricular septal defect and 4 percent for tetralogy. In Keith's long term follow-up[6] the respective incidence rates were 28 and 11 percent. On the basis of examination of a large series of chest roentgenograms the incidence rate of isolated right aortic arch has been reported to be approximately 0.1 percent.[7] Among 116 children and young adults with a right aortic arch the anomaly was unassociated with congenital cardiac disease in only 4 (3 percent). The reported incidence rate of a right aortic arch in patients with tetralogy of Fallot ranges from 13[8] to 34 percent,[7] and in patients with an isolated ventricular septal defect from 2[9] to 6 percent.[10] Aortic insufficiency, usually due to a prolapsed right aortic cusp, has been reported to occur in 2[11] or 3 percent[12] of patients with a ventricular septal defect.

Intracardiac anomalies associated with right aortic arch: In light of other reported experiences, our 12 patients with a right aortic arch also had an unusual incidence of associated intracardiac anomalies. When

the aorta ascends on the right and descends anteriorly and to the right of the trachea and esophagus, congenital heart disease is almost invariably present.[13,14] In contrast, in our group with ascent and descent of the aorta on the right, three had no evidence of heart disease.

When the aorta ascends on the right and crosses posterior to the esophagus to descend on the left, associated intracardiac disease is extremely uncommon.[13,14] However, a ventricular septal defect was present in our two patients with a right-sided ascending aorta and a retroesophageal segment and in both patients the left subclavian artery arose as the fourth branch from the descending aorta. In one patient, as commonly occurs, the ascent of the right aortic arch was higher than normal, but the apex of the arch was below the clavicle. The other patient had a cervical aortic arch—an uncommon cardiac malformation that has been described in only 18 patients, none of whom had an intracardiac defect.[15]

Comparison with other cardiofacial syndromes: Exclusive of cardiofacial abnormalities resulting from known chromosomal defects or from known teratogenic agents, three "cardiofacial"syndromes merit comment for comparison.

Patients with the Williams' syndrome[16] present with supravalvular aortic stenosis, mental retardation and a characteristic facies typified by widely spaced eyes; broad, depressed nasal bridge; heavy cheeks; a wide mouth with course pouting lips, and elfin-like ears. Patients with presumed variants of the Williams' syndrome, all with mental retardation and similar facies but with pulmonary valvular dysplasia,[17] supravalvular pulmonary stenosis[18] or discrete subvalvular aortic stenosis,[19] have also been described.

In the Noonan syndrome[20,21] there is commonly, although not invariably, mental retardation and a facies characterized by hypertelorism; a short, webbed neck; low-set ears; and a low posterior hairline. Cardiac manifestations are usually pulmonary stenosis with or without an atrial septal defect,[21] cardiomyopathy[22] or asymmetric septal hypertrophy.[21,23]

In neither syndrome does the facies resemble that of patients with the velocardiofacial syndrome or is palatal clefting present. A right aortic arch has not been noted in any patient with either syndrome; ventricular septal defect has occurred only infrequently in the Noonan syndrome.[21]

The DiGeorge syndrome, or third and fourth pharyngeal pouch syndrome,[24,25] although characterized by absence or hypoplasia of the thymus and parathyroids with cellular immune deficiency and hypocalcemia, has many features resembling those seen in the velocardiofacial syndrome. Clefts of the lip, palate or uvula may occur. Most patients who survive infancy are mildly to moderately retarded. The facies, although somewhat similar (hypertelorism, low-set malformed ears and a short jaw), shows a shortened philtrum causing a "fish mouth." Cardiac malformations relate primarily to anomalies of the third and fourth branchial arches and there is an unusually high incidence rate of interrupted aortic arch, persistent truncus arteriosus, aberrant right subclavian artery and right aortic arch with or without intracardiac malformations.

Familial and other etiologic factors: In most of our patients the syndrome presented as a sporadic occurrence in an otherwise normal family. However, there were three instances of familial occurrence. In all three patients, the features were transmitted maternally in a dominant pattern. The etiology of the velocardiofacial syndrome based on these cases of familial transmission would appear to be genetic, and more specifically dominantly inherited. Because these familial cases were transmitted maternally, it is not possible to determine if the gene is autosomal or X chromosome-linked. However, the severity of the syndrome is fairly similar among male and female children. Thus, even though X chromosome-linked dominant transmission is possible, it would tend to support probable autosomal dominant transmission.

The large number of sporadic cases may be explained in several ways. Because the patients are intellectually impaired, there is reduction of the genetic fitness of many persons with the syndrome who, therefore, become unlikely to reproduce. Most of the patients are still below reproductive age, thus limiting the current opportunity to observe the possible effects of a dominant gene.

Finally, we cannot rule out etiologic heterogeneity. There were four unaffected mothers who had been given progestational agents during the early first trimester of pregnancy and one who had been exposed to anesthetic gases during pregnancy. The possible teratogenic effects of these substances in relation to the development of the velocardiofacial syndrome is possible but unproved.

Sphygmolog

the practical approach to ambulatory blood pressure recording

Patent Pending

Comfortably worn on belt or shoulder strap.

Size 1 1/4" x 3 1/2" x 6 1/4" Weight 14 ounces

No playback time or equipment required.

Direct reading recorder provides a graphic recording on a 3 inch diameter circular chart of the systolic and diastolic pressure over a 12 or 24 hour period.

For a demonstration or further information write or call collect

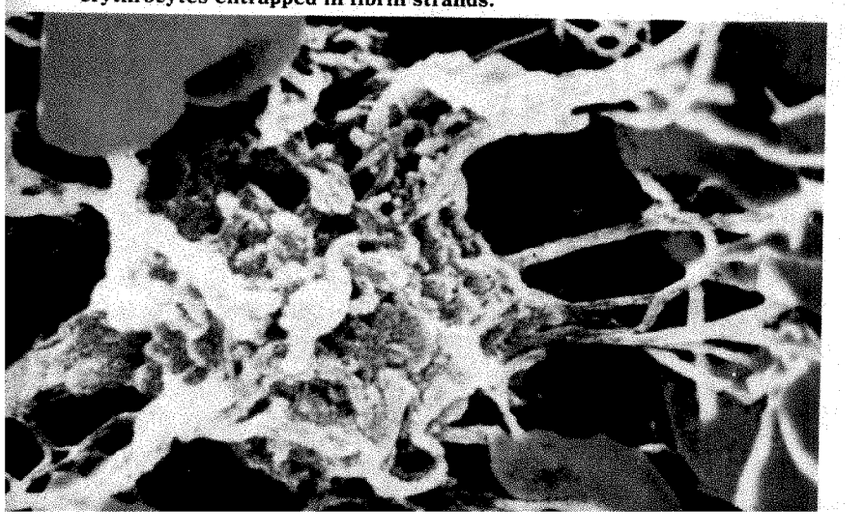
Update on Oral Anticoagulation

TREATING MYOCARDIAL INFARCTION AND REDUCING THE THREAT OF THROMBOEMBOLISM

Each year in this country approximately one million people suffer acute myocardial infarctions. Rapid emergency treatment in coronary care units has been credited with reducing by up to one third the mortality among patients hospitalized with acute attacks.[1]



Thrombosis—incidence in myocardial infarction Following the damage to the heart itself, thromboembolism is perhaps the most serious sequel to myocardial infarction.

A study has demonstrated that there is a 39% incidence of calf vein thrombosis during the acute phase of myocardial infarction.[1]

Speed saves lives It has been reported that more than half the thrombi destined to occur in the calf veins form within 72 hours of myocardial infarction, and three-fourths form within the first week. Therefore, a number of investigators have recommended that antithrombotic measures should begin upon admission to the hospital and be effective almost immediately.[2]

Oral anticoagulants have a clinical value It has also been stated that the use of anticoagulants may reduce the frequency of calf vein thrombosis from 22 to 6.5%. The use of anticoagulants is subject to differing opinions regarding improved survival. A number of authorities recommend the use of anticoagulants in *all* patients who have no specific contraindications during the period of hospitalization.[1]

Scanning electron micrograph of 'Red' thrombus, formed by erythrocytes entrapped in fibrin strands.

One team of investigators in M.I. recommends pr viding full-dose warfarin while the patient is in th hospital and for several days afterward—

if the patient has had prior infarcts or thromboembolism
if the area of infarction is large
if complications (such as CHF or hypotensio require prolonged bed rest.

But, if post myocardial infarction syndrome (Dressler's syndrome) develops, anticoagulants should be discontinued, as pericardial hemorrhage even cardiac tamponade may develop.[1]

Objectives and benefits of anticoagulation T use of anticoagulants in the acute phase of myocar dial infarction has these potential advantages:[2]

prevention of deep vein thrombosis
reduction of embolization from cardiac mural thrombi
prophylaxis against extension of myocardial necrosis or long-term recurrence of infarction
reduction of overall mortality

If anticoagulants can inhibit the formation of deep vein thrombi, then the incidence of pulmonar embolism might be diminished—and pulmonary em lism has been estimated as a threat to life in 5,000 of the 500,000 myocardial infarction patients who are admitted to hospitals in this country each year

A look at survival One retrospective study of the use of anticoagulants in M.I. evaluated the survival of 1,307 patients from 20 hospitals in a large metropolitan community. The diagnosis of M.I. was based on predefined criteria, which includ typical chest pain, serial ECG's, enzyme elevations, and autopsy findings.

Among anticoagulated patients, the adjusted in-hospital case-fatality rate was 18%. For patients who did not receive thi treatment, the fatality rate was 31%. For survivors followed for as long as ten years patients who had been anticoagulated still fared better than those not so treated.[3]

The authors of this study recognize

the drawbacks of using retrospective evidence and call for the formation of a multi-center, double-blind, randomized study on the use of anticoagulants in acute myocardial infarction.

Screening the high risk group The risk of DVT (deep vein thrombosis) is particularly great among certain patient groups:

- patients with left ventricular failure
- patients in shock
- patients with arrhythmias
- older patients
- obese patients
- patients with varicose veins
- patients with previous myocardial infarction or thromboembolism

Screening techniques Diagnosis of DVT by physical examination may miss a significant number of clinically silent thrombi. There are, however, additional technological tools to help the clinician define more accurately the incidence of deep vein thrombosis. Among these are:

iodine-125 fibrinogen scanning—radioactively tagged fibrinogen is incorporated into actively forming thrombi and is detected on external sensors. This method is accurate for popliteal and calf vein thrombi, but not for iliofemoral thrombi.[2]

Phlebogram showing occlusion in deep vein of the upper calf.

venography—radiographic evidence of DVT is seen as a constant filling defect in venous projections, abrupt termination of a column of contrast material at a constant site, nonfilling of the deep veins, and presence of flow in collateral veins.[4]

ultrasound—Doppler ultrasound scanning can provide a fast, convenient, inexpensive reading of deep venous obstruction. This technique is potentially the most versatile and accurate method available. However, it demands considerable operator experience to insure maximal accuracy.[5]

impedance plethysmography—this technique results from the observation that blood volume changes in the calf produced by inflation or deflation of a thigh cuff produce variations in electrical resistance (impedance). Such changes are reduced in patients with thrombosis of the popliteal or more proximal veins.[4]

Patient compliance through education Providing the anticoagulated patient with information about his altered physical state and motivating him to comply with the therapeutic regimen constitute one of the most important aspects of health care.[6]

To determine the best way of imparting necessary information about anticoagulation to patients, a test was devised. One group of patients was given a brochure detailing the need for the medication and the importance of following the doctor's instructions. A second group of patients was given a programmed instruction booklet which was quite comprehensive in its teaching content, which included the action of warfarin, the purpose of prothrombin times, how to figure dosage from tablet strengths, possible complications and steps to take to control them.

When tested for learning and retention, the patients in the programmed instruction group scored significantly higher than the group given brochures only. In an area of medicine that relies so heavily on patient compliance, this report could be important in determining how medical information is communicated to the patient.[6]

The bottom line A postmortem study[7] underlines the importance of thrombosis in myocardial infarction. In this study of 173 patients with recurrent myocardial infarction, coronary occlusion due to thrombosis occurred in 54% of cases. Recent occlusive coronary thrombosis was 4 times less frequent in patients who received adequate anticoagulation (mean prothrombin level was 29 ± 5%).

And as one authority states:

"Rational use of anticoagulant therapy in the setting of acute myocardial infarction may save more than 8,000 lives a year in this country. Full advantage should be taken of this therapeutic opportunity."[2]

IREX

Systems that break the ultrasound barriers.

ex is making breakthroughs in echocardi-
graphy. Technological breakthroughs.
reakthroughs that provide crisper images.
lore diagnostic capability. Greater flexi-
ility. And all at breakthrough prices.

ex Phased Array Real Time Imaging System

namically focused 2-D sector scanner featuring unique 32 channel
rformance. Plus two sector-derived M-modes and a totally inde-
ndent M-mode. Compact, electronically steered, lightweight trans-
cers. Optional heart sound/pulse and respiration module. Integral,
vanced design Sony® Beta format video cassette recorder. Simulta-
ous 2-D and M-mode black and white hard copy. And more.

ex Cardio 80® Graphics Analyzer

eractive quantitative analysis of two-dimensional images, M-mode
hocardiograms and other cardiodiagnostic data. 2-D analysis from
play screen video or hard copy. Immediate printout of results. User
ogrammable for analysis of research and special applications data.
d more.

Technology. Innovative recording and display systems specifically designed for the cardiologist. Flexible, highly sensitive echo amplifier. Dynamically focused phased array. Ultrahigh resolution. Microprocessor control. State-of-the art, phased array transducers. Software updating. High-speed digital scan conversion. All Ire designed. All Irex built. So you get leading-edg performance for improved diagnostic images.

Versatility. Broadest range of cardiac diagnostic capabilities in each Irex system. Highly flexible signal processing controls. So you can perform and analyze the study you want, the way you want to do it.

Mobility. Compact, durable systems that go where you need them, when you need them.

Commitment. The Irex commitment assures quality, reliability, continuing attention; prompt service from factory-trained Irex representatives; on-site training. So you get the most out o your Irex system.

Value. Irex systems give you features and sophistication that would cost you thousands more elsewhere.

Breakthrough technology at breakthrough pric is what Irex echocardiography is all about. Return the coupon today for more ultra-exciting information.

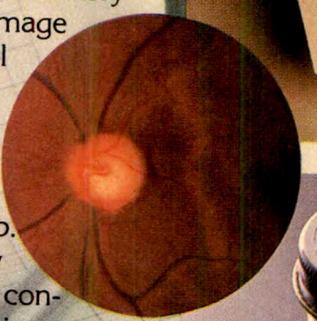
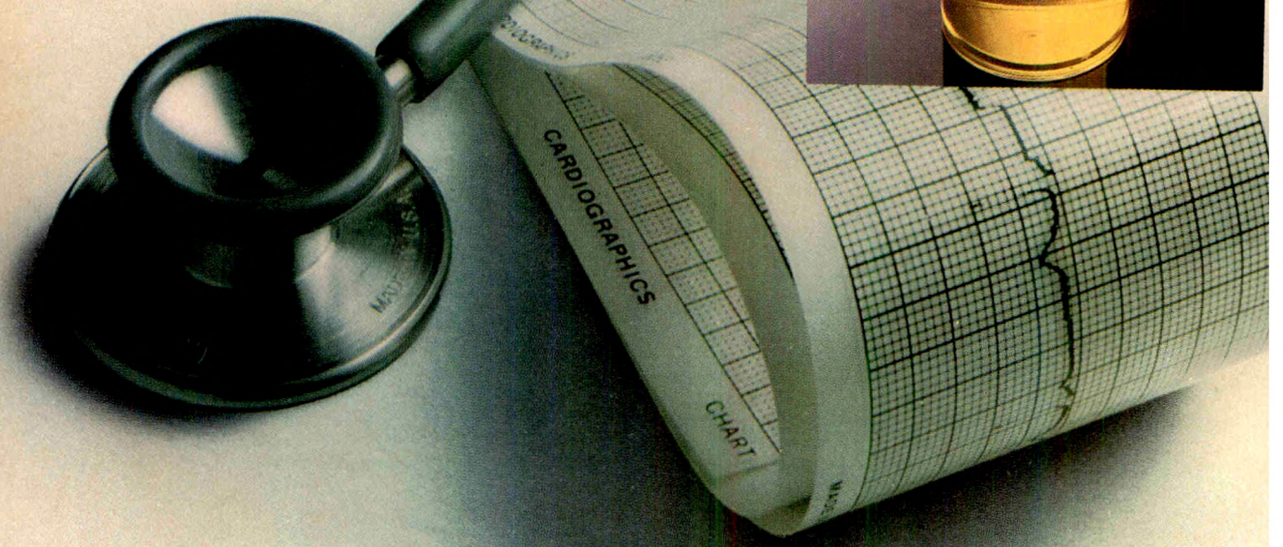
AJC-10



AFTER A THOROUGH WORKUP

HYPERTENSION MAY BE YOUR DIAGNOSIS OF HIS PHYSICAL CONDITION



On three different visits, the patient's readings have hovered about the 150/95 mmHg level. Both his father and uncle are currently being treated for high blood pressure; a paternal grandfather died in his 60's of a stroke. Neither the physical examination nor the laboratory workup indicates target organ damage or coexisting disease. Cholesterol levels (250 mg/dL) are on the high side, however.

The patient is 30 pounds overweight, smokes several cigars a day, and has a sedentary office job. He admits he likes his food highly spiced—and over-salted. Besides considering appropriate antihypertensive agents, you may also wish to design a treatment program that includes weight control, salt restriction and exercise.

ROCHE

ANXIETY MAY WELL BE YOUR DIAGNOSIS OF HIS PSYCHOLOGICAL CONDITION

During these visits, you also have observed symptoms of excessive tension and anxiety in this patient—restlessness, irritability, apprehension. His history lists anxiety-related insomnia.

Should this anxiety persist, despite your reassurance and counseling, adjunctive Valium® (diazepam/Roche) can be especially helpful. Valium provides prompt and dependable calming action. Within days, it helps reduce anxiety to manageable levels. And Valium is generally well tolerated. Side effects more severe than drowsiness, fatigue and ataxia are rare and seldom serious. As with all CNS-acting agents, patients should be cautioned against drinking alcoholic beverages or driving while on Valium therapy. Periodic reassessment of the need for psychotropic medication is also recommended.

WHEN ANXIETY IS ALSO A NEWLY DIAGNOSED PROBLEM

Before prescribing, please see summary of product information on next page.

Substitution Permi

VALIUM®
(diazepam/Roche)

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.
Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.
Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice, periodic blood counts and liver function tests advisable during long-term therapy.
Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).
Supplied: Valium® (diazepam/Roche) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available in trays of 10.

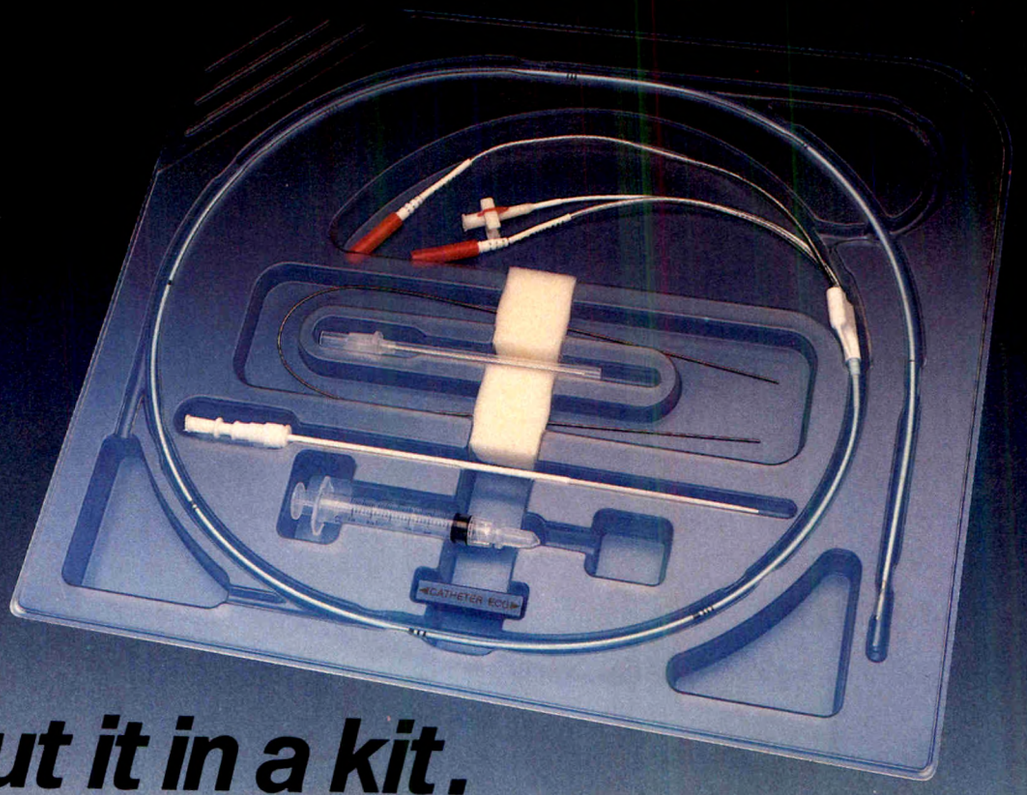
Nutley, New Jersey 07110

When the compromised arrhythmic patient needs round-the-clock, year-after-year protection



324 mg Quinaglute® DURA-TABS®
(quinidine gluconate)

CONTRAINDICATIONS:
Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.
Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening.
Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects, ventricular premature beats, ventricular tachycardia or flutter while on the drug.
Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.
Idiosyncrasy or hypersensitivity to quinidine.
WARNINGS:
In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.
PRECAUTIONS:
The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.
Quinidine in large doses may reduce the contractile force of the heart, therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication. The potential disadvantages and benefits must be weighed.
It should be administered cautiously, if at all, to senile patients.
Hospitalization for close clinical observation, electrocardiographic monitoring, and possibly plasma quinidine levels is indicated when large doses are used or with patients who present an increased risk.
ADVERSE REACTIONS:
Symptoms of cinchonism, ringing in ears, headache, nausea, disturbed vision may appear in sensitive patients after a single dose of the drug.
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism, hypotension.
Gastrointestinal: Nausea, vomiting, abdominal pain, diarrhea.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision fields, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Cutaneous flushing with intense pruritus.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.
See package insert for full information.

maintenance therapy

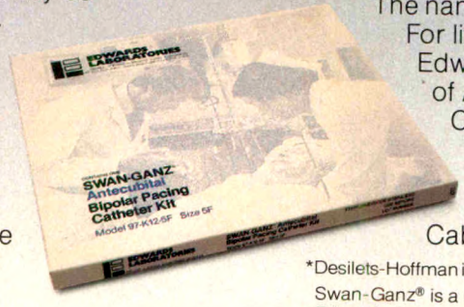
How do you improve on the Swan-Ganz® Pacing Catheter?

Put it in a kit.

The Swan-Ganz Bipolar Pacing Catheter has been shown to provide excellent pacing stability and is well known for its ease of insertion. Now you can get this proven performance with all the convenience of a ready-to-use kit.

A rapid, reliable bedside procedure.

Clinical experience has shown that insertion can be performed at bedside in minutes by using an ECG recording from the distal electrode as a placement guide. Blood flow directs the balloon-tipped catheter rapidly into the right ventricle. No fluoroscopy is needed. Both the catheter body and electrodes are radiopaque and may be visualized by fluoroscopy, if desired.



Quality components for quality pacing.

In addition to the 5-F Swan-Ganz Bipolar Pacing Catheter, the kit contains the basic components needed for prompt, reliable catheter placement: a Desilets-Hoffman* type percutaneous insertion set for maximum ease in insertion, a unique syringe designed to ensure proper balloon inflation and a convenient ECG adapter.

Two types of kits are available. One is designed for antecubital, subclavian or internal jugular vein insertion. The other, for femoral insertion, has a "J" shaped tip to facilitate entry from the inferior vena cava. Either may be used with most external pacemakers.

So now get reliable emergency pacing and ease of insertion with all the convenience of a ready-to-use kit.

The Swan-Ganz Bipolar Pacing Catheter Kit. The name to rely on for quality pacing.

Boston, Massachusetts

Forty-three of 1,312 men aged 35 to 54 years in the Framingham Offspring Study had clinically recognized coronary heart disease at the initial examination. Twenty-six men in this group had previously had a myocardial infarction. Of 1,296 women in the same age range, only 11 had coronary disease and 3 a prior myocardial infarction. The prevalence of coronary heart disease in men was strongly associated with age, smoking, high density lipoprotein (HDL), low density lipoprotein (LDL) and total cholesterol using univariate analyses. When multivariate logistic regression analysis was used, age, smoking and HDL and LDL cholesterol retained their significant association with coronary heart disease. The total cholesterol/HDL cholesterol ratio was also strongly associated with coronary heart disease in the multivariate analysis. It is concluded that both HDL and LDL cholesterol are strongly and independently associated with the prevalence of coronary heart disease, whereas the level of very low density lipoprotein cholesterol makes no statistically significant independent contribution.

The relation of serum lipid and lipoprotein levels to clinically recognized coronary heart disease is an area of increasing research. Much of our understanding of the epidemiology of cardiovascular disease has accrued from the experience of several long-term prospective studies in which cases have been documented and related to commonly measured variables such as smoking, blood pressure and serum cholesterol concentration. However, many of the recent studies lacked lipoprotein cholesterol data for men and women less than 50 years old. Not enough is known about the relation between lipids and coronary heart disease in the younger population. One recently reported study[1] showed little relation between HDL cholesterol level and coronary heart disease in a group of men under age 45 years. Similarly, data are scarce relating, with use of multivariate techniques, the prevalence of these diseases to factors such as blood pressure, smoking, obesity, alcohol consumption and lipoprotein cholesterols.

This study is based on data obtained at the first examination of the Framingham Offspring Study. The results for prevalence of coronary heart disease and myocardial infarction are reported. Multivariate analysis was performed using coronary risk factors and various lipoprotein cholesterol subfractions in an effort to determine the association of these variables with cardiovascular outcomes in this relatively young population.

Methods

Study group: The study design, methodology and description of the Framingham Offspring Study sample are provided elsewhere.[2,3] The results of this report are confined to men and women aged 35 to 54 years when examined in 1971 to 1975. All subjects were either offspring (1,688 participants) or spouses of the offspring (918 participants) of the original Framingham Heart Study cohort. The historical data collected included history of coronary heart disease, smoking habits and alcohol use recorded at the time of a clinic visit that included

a physical examination. Serum lipoprotein cholesterol levels were measured with the Lipid Research Clinic protocol, and an electrocardiogram at rest was performed at the examination.

Cholesterol determinations: Serum cholesterol was measured using a manual Abell-Kendall procedure.[4] A heparin manganese-chloride precipitation technique was used to determine the high density lipoprotein (HDL) cholesterol.[5] Low density lipoprotein (LDL) cholesterol was calculated by subtracting the HDL cholesterol from the bottom fraction cholesterol, measured after reconstitution of the bottom fraction after preparative ultracentrifugation of ethylenediamine tetraacetate plasma at serum density. The very low density lipoprotein (VLDL) cholesterol was measured by subtracting the bottom fraction cholesterol from the total cholesterol. The ratios of total cholesterol to HDL cholesterol and of LDL cholesterol to HDL cholesterol were calculated for each subject. Height and weight for each participant were determined with the subject dressed in an examining gown, wearing no shoes.

Historical data: The medical history included specific questions designed to elicit the usual consumption of alcohol. Intake of beer (number of 12 ounce cans × 0.44), wine (number of 4 ounce glasses × 0.40) and cocktails (1.5 ounce liquor × 0.57) intake was summed to achieve an overall measure of weekly alcoholic consumption.[6] The Metropolitan Life Insurance relative weight was calculated for each person from published tables.[7] The criteria for the diagnosis of myocardial infarction and coronary heart disease used in this study are described elsewhere.[8]

Statistical analysis: The univariate relation between coronary heart disease and various factors was tested by the *t* test assuming equal variances. The chi-square test was utilized for cigarette smoking. The statistical tests for the association of the specific independent variables with the dependent variable coronary heart disease employed multivariate logistic regression using the Walker-Duncan estimation method.[9] No regression analyses were performed for the women because there were too few cases of myocardial infarction or coronary heart disease.

Results

Prevalence of coronary heart disease: Among the 1,312 men examined in the Framingham Offspring Study who were 35 to 54 years old, 43 had had coronary heart disease, and 26 had a history of myocardial infarction. Among 1,296 women participants in the study in the same age range, 11 had coronary heart disease, including 3 with a myocardial infarction. There were no instances of coronary heart disease in offspring less than 35 years old at the time of the examination. The age- and sex-specific prevalence rates summarizing these results are presented in Table I. Next to these results are those for participants in the original Framingham cohort when they were sampled in 1948 to 1951.

The age-adjusted rates of coronary heart disease given for each of the sex-specific groups in Table I allow comparison between parents and offspring. The rate for men in the original cohort was 18/1,000. After direct adjustment to the cohort age distribution, the rate for the offspring was 29/1,000. The age-adjusted prevalence rates of coronary heart disease for women were 7/1,000 in the original cohort and 8/1,000 in the offspring. Because the data suggested differences between the cohort and the offspring, Mantel-Haenszel chi-square statistics were calculated using 5 year age stratifications to compare the men in the cohort with the men in the offspring ($\chi^2 = 3.80$) and the women in the two groups ($\chi^2 = 0.01$).

Coronary heart disease and abnormal lipoprotein profile: Some of the men and women with coronary heart disease had abnormal lipoproteins when classified according to the Fredrickson criteria.[5] These data are summarized in Table II for the separate Fredrickson classes, coronary heart disease diagnoses and sex. Among the 43 men with coronary heart disease, type IV hyperlipoproteinemia occurred in 11 and was twice as common as type II (5 men). Of the 11 women with coronary heart disease, 2 had type II and 1 had type IV hyperlipoproteinemia. The sole woman with a history of myocardial infarction who had an abnormal lipid profile was classified as having type II hyperlipoproteinemia.

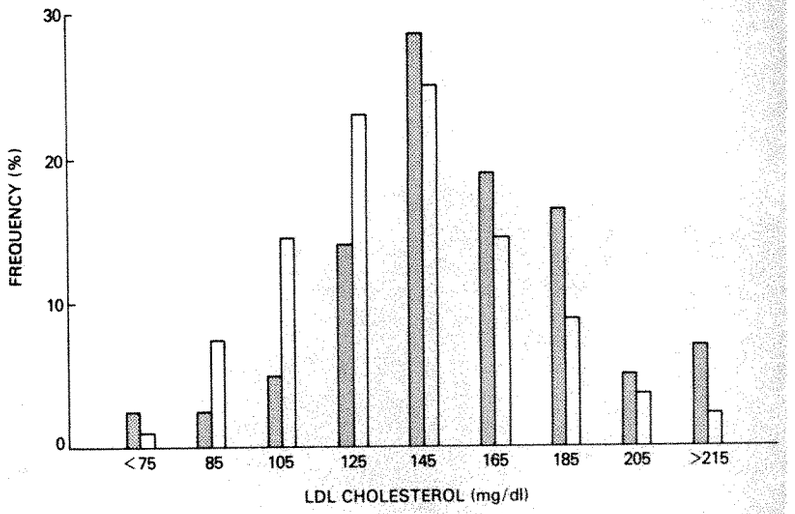

FIGURE 1. Frequency distributions of LDL cholesterol levels in men with (**stippled bars**) and without (**white bars**) coronary heart disease: Framingham male offspring aged 35 to 54 years.

Individual variables in coronary heart disease: The mean values for several variables measured for subjects with and without coronary heart disease are given in Table III. Univariate *t* tests were used to test for differences between the means. The mean values for total cholesterol, LDL cholesterol, HDL cholesterol and total cholesterol/HDL ratio showed significant differences in the two groups as did age at examination and reported cigarette use. Subjects with coronary heart disease had higher values for total and LDL cholesterol, but lower values for HDL cholesterol than those of the subjects without coronary disease.

A history of current or previous smoking was much more prevalent in the group with than in the group without coronary heart disease (95 percent versus 72 percent). The other variables tested showed no signficant differences in the two groups.

Multivariate regression coefficients in coronary heart disease: Table IV presents the standardized multivariate logistic regression coefficients for coronary heart disease and myocardial infarction in men aged 35 to 54 years. The regression analysis was performed with the independent variables—age, alcohol use, history of cigarette smoking, Metropolitan relative weight, systolic blood pressure, HDL and LDL cholesterol. Age, cigarette use, HDL and LDL cholesterol, all of which are significantly associated in the univariate case, retain their association with coronary heart disease when entered in a multivariate regression equation. From this same list of variables, only age and HDL cholesterol were significantly associated with myocardial infarction.

Frequency distribution of various lipoproteins: The frequency distribution of various lipoproteins in men 35 to 54 years old with and without coronary heart disease are presented in histograms. The distribution of LDL cholesterol in men with coronary disease showed a marked shift and 75 percent of this group had LDL cholesterol values that exceeded the mean LDL cholesterol value for the men without coronary disease (Fig. 1). There was little evidence for different variation in the two groups, and neither distribution showed dramatic skewness.

TABLE III

Mean Levels of Variables in Men With and Without Coronary Heart Disease (CHD): Framingham Male Offspring, Aged 35 to 54 Years

Variable	Men With CHD	Men Without CHD

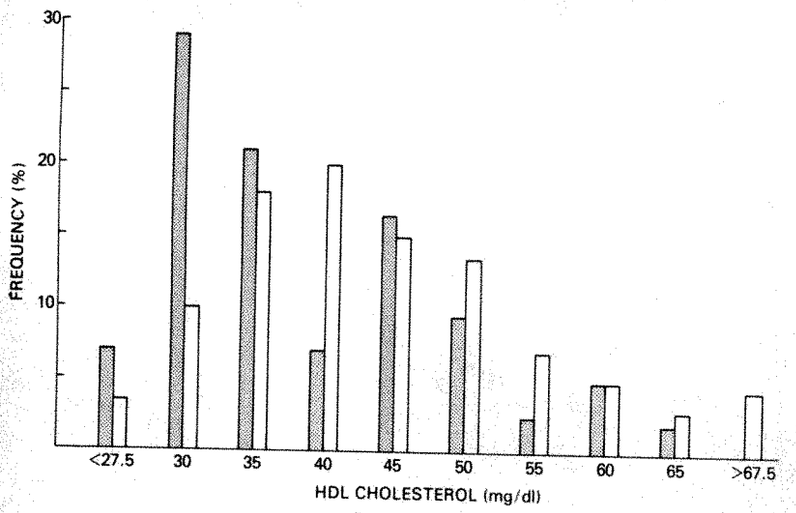

FIGURE 2. Frequency distributions of HDL cholesterol levels in men with (**stippled bars**) and without (**white bars**) coronary heart disease: Framingham male offspring aged 35 to 54 years.

Figure 2 shows the frequency distribution of HDL cholesterol in the men with and without coronary heart disease. Approximately 55 percent of the men with disease had a low value for HDL cholesterol (less than 35 mg/dl) and in none did the level exceed 68 mg/dl; in approximately 5 percent of the men without coronary disease the level exceeded this value.

The relative frequencies of various total cholesterol/HDL ratios in men with and without coronary heart disease are shown in Figure 3. The distribution of the ratio shows slight skewness toward higher value in men without coronary disease and a marked skewness to lower values in the men with disease. Approximately 65 percent of the men with coronary disease had a total cholesterol/HDL ratio greater than 5.5, compared with only 35 percent of the men without disease.

Table V summarizes the associations of high LDL cholesterol (more than 150 mg/dl) and low HDL cholesterol in men with and without coronary heart disease.

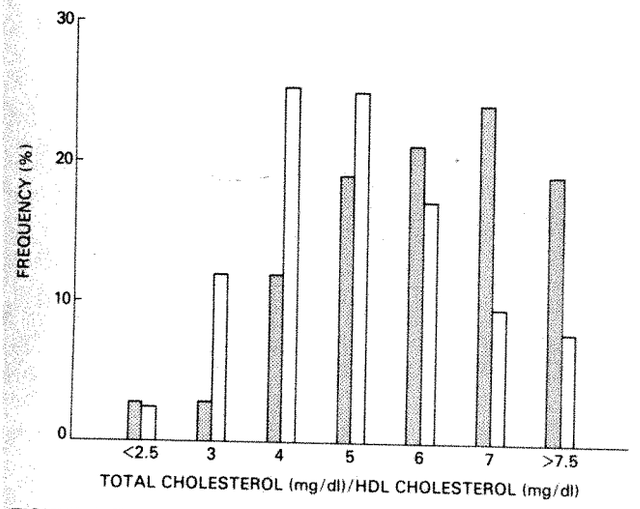

FIGURE 3. Frequency distributions of values for total cholesterol/HDL cholesterol ratio in men with (**stippled bars**) and without (**white bars**) coronary heart disease: Framingham male offspring aged 35–54 years.

In each instance, the men with disease are more likely to have these extreme values. High LDL and low HDL cholesterol in the same person was much more common among the men with disease.

Discussion

Prevalence of coronary heart disease in past 2 decades: This report demonstrates that coronary heart disease is still a highly prevalent disease in Framingham, Massachusetts. The original cohort was first seen in 1948 to 1951, and their offspring were examined from 1971 to 1975. Over that 20 year span the national mortality rates for coronary heart disease have escalated, peaked and declined since the late 1960's. Not enough is known about the trend in prevalence of coronary heart disease over the past 2 decades. Many of the published comparisons are based on health statistics, and comparability suffers because of changes in diagnostic methods and criteria as well as population shifts.[10]

Previous comparison of the cohort and offspring[11] has demonstrated striking reductions in cigarette smoking, and modest but statistically significant reductions in total plasma cholesterol levels. However, the Mantel-Haenszel analysis applied to 5 year age groups showed that the proportion of men with coronary heart disease was significantly greater among the offspring than in the cohort.

Recent publications have discussed the decline in coronary heart disease mortality, and investigators have queried whether that phenomenon stems from a decrease in case fatality, a decline in the incidence or some combination of these two effects.[10] The increased prevalence among the offspring supports the former contention, but such conclusions should be drawn with caution, especially when reductions in major risk factors that would be likely to decrease incidence are apparent. Previous analysis[11] showed that parents of children who did not participate in the offspring study were no different from the parents of those who did participate. However, it is possible that increased health awareness among men in the offspring generation led to a greater

participation among subjects with clinically recognizable coronary heart disease. Such a trend involving a small proportion of the sample would not be detectable when comparing parents of participants and nonparticipants.

Contribution of hyperlipoproteinemia to prevalence of coronary heart disease: Hyperlipoproteinemia, especially hyperbetalipoproteinemia, has been shown to contribute greatly to the frequency of coronary heart disease in young adults.[12] The contribution of hyperlipoproteinemia to coronary heart disease occurring in the 5th and 6th decades is also thought to be considerable.[13] In our study (Table II), approximately one third of the men and women with coronary heart disease and myocardial infarction had abnormal cholesterol or triglyceride levels as assessed with the Fredrickson criteria. Our results show that these classifications are associated with coronary heart disease, but they are not present within the majority of the group with coronary disease in this age range, as about two thirds of our men and women with coronary heart disease had "normal" lipoprotein cholesterol levels. Of course, offspring who have died of coronary heart disease are not included in this report. It is possible that those persons are more likely to have had such elevations of lipoprotein levels.

Our data (Table III) emphasize the importance of lipoprotein cholesterol quantification in showing an association between these variables and coronary heart disease in men less than age 54 years. Previously, total serum cholesterol was shown to be associated with coronary heart disease in subjects under age 50 years and to lose its predictive power in the older age groups.[14] Our data indicate significant univariate associations for HDL and LDL as well as total cholesterol. These results are similar to those of other studies in Israel,[1] Sweden,[15] Framingham,[16] and Honolulu,[17] and Evans County.[17]

Multivariate analysis of risk variables: Some of the variables that are highly associated with coronary heart disease in the univariate case lose their significance in the multivariate analysis. For the variables shown in Table IV, only age, history of cigarette use and HDL and LDL cholesterol levels retain their strength in contributing significantly to the association with coronary heart disease. A similar result is obtained when myocardial infarction replaces coronary heart disease as the dependent variable in the logistic equation. In this case, a previous history of smoking and LDL cholesterol are not significantly associated with coronary heart disease. However, the coefficients do remain positive. If the total cholesterol/HDL ratio is substituted for HDL and LDL cholesterol levels, and the other variables are retained, similar results are obtained and the total cholesterol/HDL ratio is significantly associated with coronary heart disease and myocardial infarction in the multivariate case. If VLDL cholesterol is added as an independent variable in this multiple regression, no significant independent role is demonstrable over and above the associations of HDL and LDL cholesterol levels. The association of the independent variables in Table IV and coronary heart disease is shown in Figure 4. The quintile of risk from the multivariate regression coefficients of Table IV is used to predict the actual number of cases of coronary heart disease.

TABLE V

Associations of Low HDL Cholesterols and High LDL Cholesterols With Coronary Heart Disease (CHD): Framingham Male Offspring, Aged 35 to 54 Years

	Men With CHD (n = 43)	Men Without CHD (n = 1267)
Low HDL cholesterol (<35 mg/dl)	20 (46%)	262 (21%)
High LDL cholesterol (<150 mg/dl)	23 (53%)	442 (35%)
High LDL cholesterol and low HDL cholesterol	9 (21%)	90 (7%)
Low LDL cholesterol and high HDL cholesterol	9 (21%)	653 (52%)

Significance of HDL decrease and VLDL cholesterol elevation: Because HDL and VLDL cholesterol show substantial negative correlation in these and other data,[18] it is possible that much of the association of VLDL cholesterol with coronary heart disease stems from the association of lower HDL cholesterol levels and coronary heart disease. When VLDL cholesterol replaced HDL cholesterol in a multiple regression, no significant association with coronary heart disease, independent of LDL cholesterol, cigarette smoking and age, was demonstrable. Thus, it appears that elevation of VLDL cholesterol and decrease in HDL cholesterol do not bear comparable information and thus have different implications for risk of coronary heart disease. However, in these data HDL cholesterol is more strongly associated with coronary heart disease than is VLDL cholesterol.

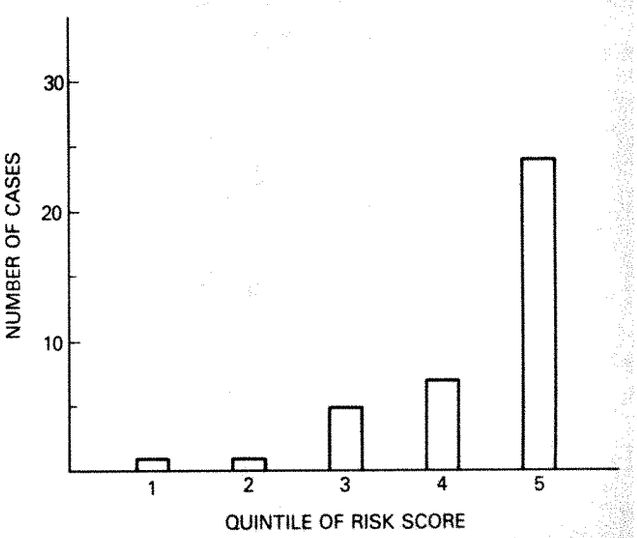

FIGURE 4. Prevalence of coronary heart disease by quintile of risk in men aged 35–54 years: Framingham Offspring Study. (Logistic regression coefficients using variables from Table IV were employed for the analysis.)

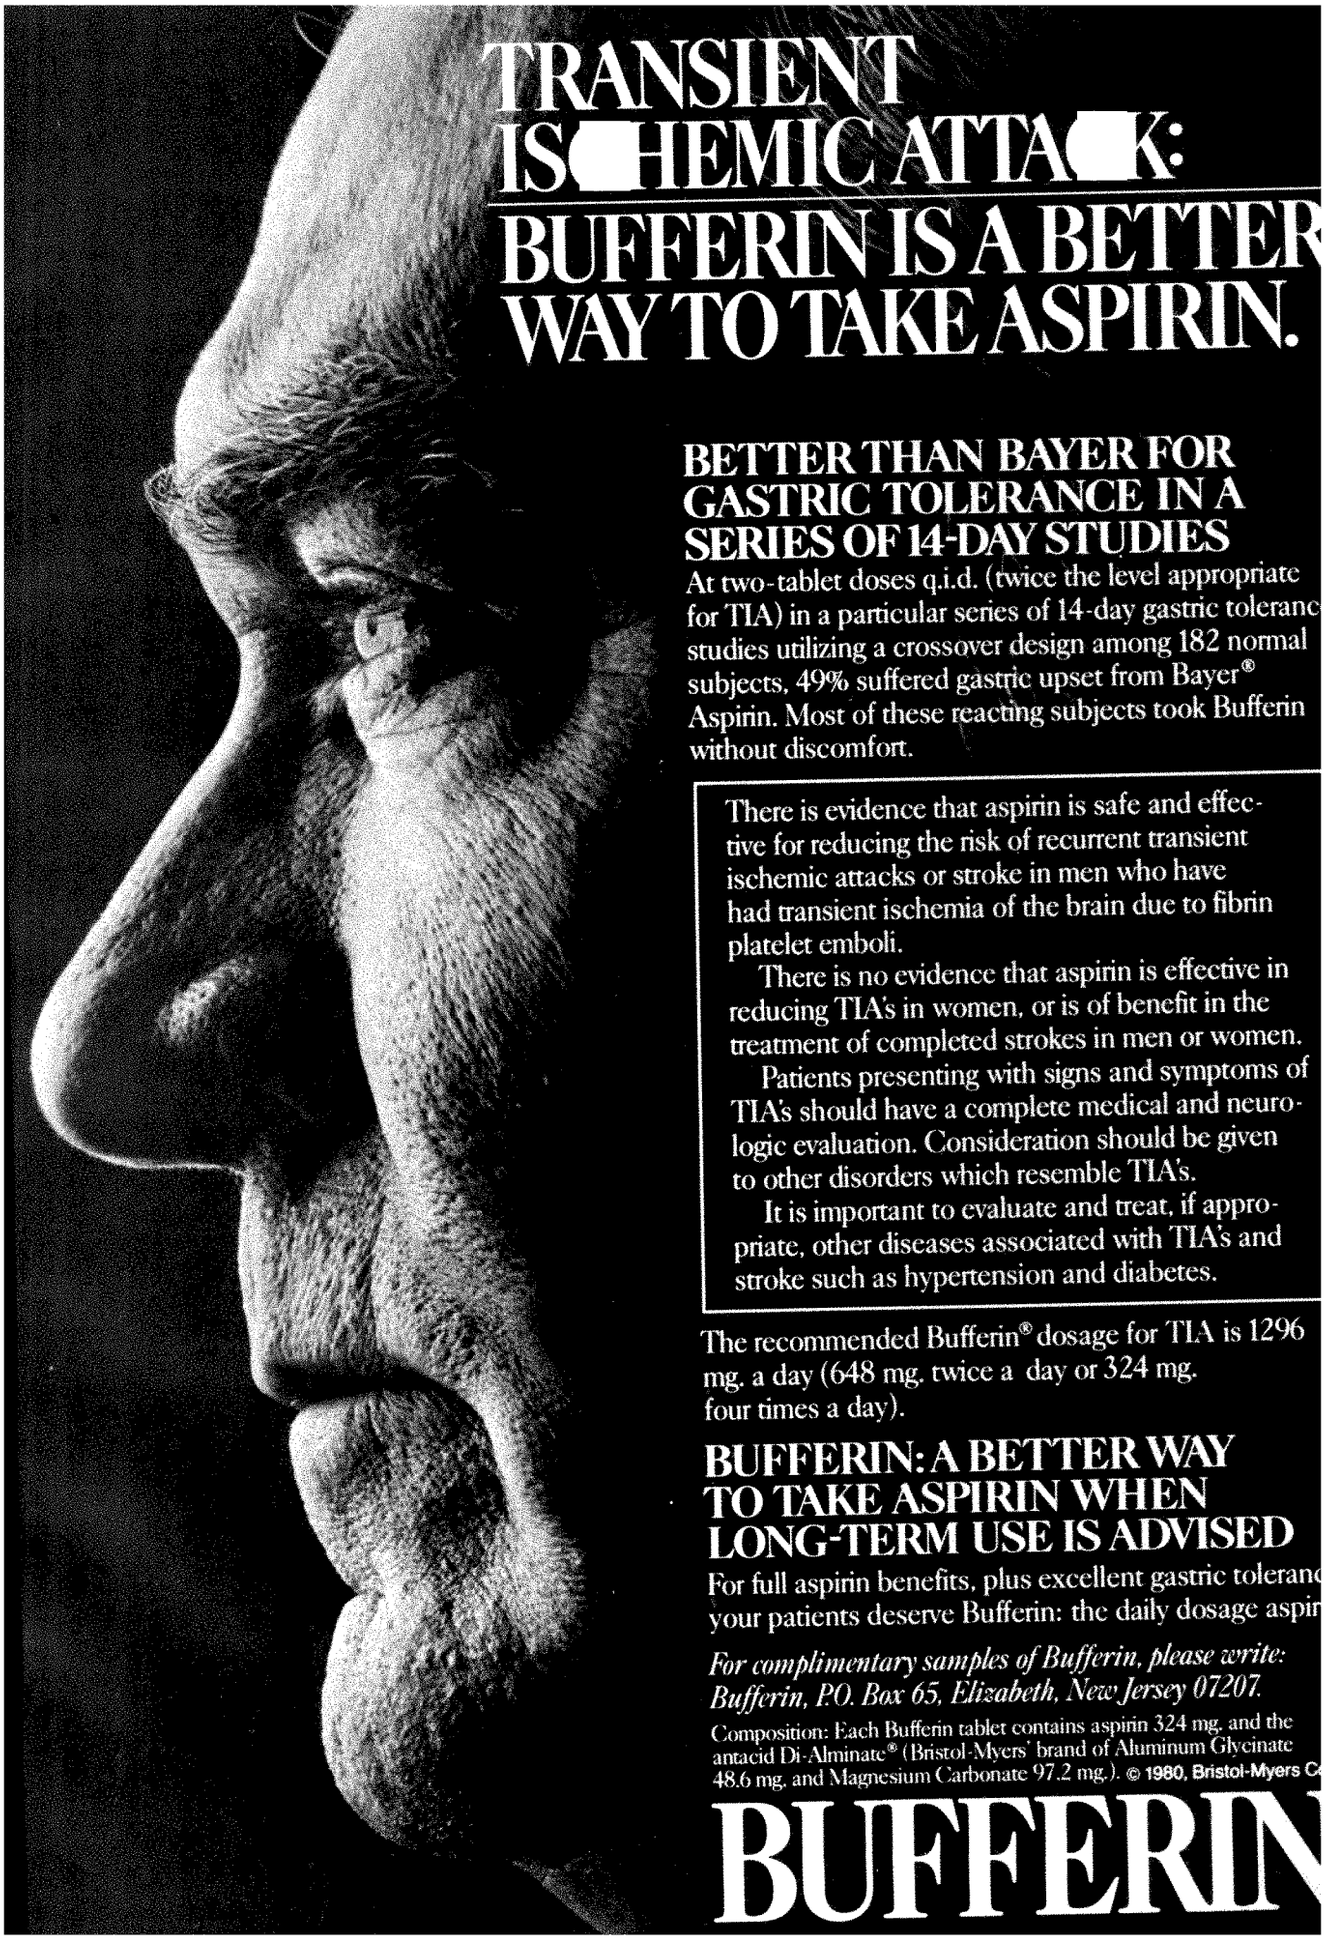

The failure to identify associations between coronary heart disease and alcohol consumption in our data should be considered cautiously. As with any data on alcohol consumption arising from personal interviews, there is suspicion of underreporting by some subjects. Given the strong relation between alcohol ingestion and HDL cholesterol,[6] it is possible that part of the association assigned by the analysis to HDL cholesterol may in fact derive from alcohol consumption, if the sample of subjects without coronary heart disease shows greater underreporting of alcohol consumption than the sample of subjects with coronary disease. Again, incidence data may add information on this subject.

Role of LDL versus HDL cholesterol: LDL and HDL cholesterol levels play important independent roles in the multiple logistic regression. Figures 1 and 2 give a visual presentation of the strengths of these associations. When either lipoprotein cholesterol was considered alone, there was no distinct separation between men with and without coronary heart disease. Total cholesterol/HDL ratio as a summary of lipoprotein quantification did not lead to an obvious separation of the two groups (Fig. 3). Furthermore, the interpretation of these data was subject to the severe limitations of prevalence data. First, any modification of life styles subsequent to the development of clinical disease might influence lipoprotein cholesterol concentrations[19-21] in a favorable manner and would have the effect of reducing the strength of association. Also, adverse lipoprotein profiles may be more likely to lead to fatal disease. Again, if this is true, the prevalence data would underestimate the true association of coronary heart disease and lipoprotein cholesterol levels.

Clinical implications: Other investigators have utilized lipoprotein summary statistics to show an association with coronary heart disease.[22] We obtained results similar to those for total cholesterol/HDL ratio when the LDL/HDL ratio was used. In an effort to give the clinician a useful index to associate lipid values with coronary disease, the total cholesterol/HDL ratio has been used. Total cholesterol is easily measured, and with improved techniques and quality control the same will probably hold for nonresearch HDL cholesterol determinations in the near future.[23]

TRANSIENT ISCHEMIC ATTACK: BUFFERIN IS A BETTER WAY TO TAKE ASPIRIN.

BETTER THAN BAYER FOR GASTRIC TOLERANCE IN A SERIES OF 14-DAY STUDIES

At two-tablet doses q.i.d. (twice the level appropriate for TIA) in a particular series of 14-day gastric tolerance studies utilizing a crossover design among 182 normal subjects, 49% suffered gastric upset from Bayer® Aspirin. Most of these reacting subjects took Bufferin without discomfort.

There is evidence that aspirin is safe and effective for reducing the risk of recurrent transient ischemic attacks or stroke in men who have had transient ischemia of the brain due to fibrin platelet emboli.

There is no evidence that aspirin is effective in reducing TIA's in women, or is of benefit in the treatment of completed strokes in men or women.

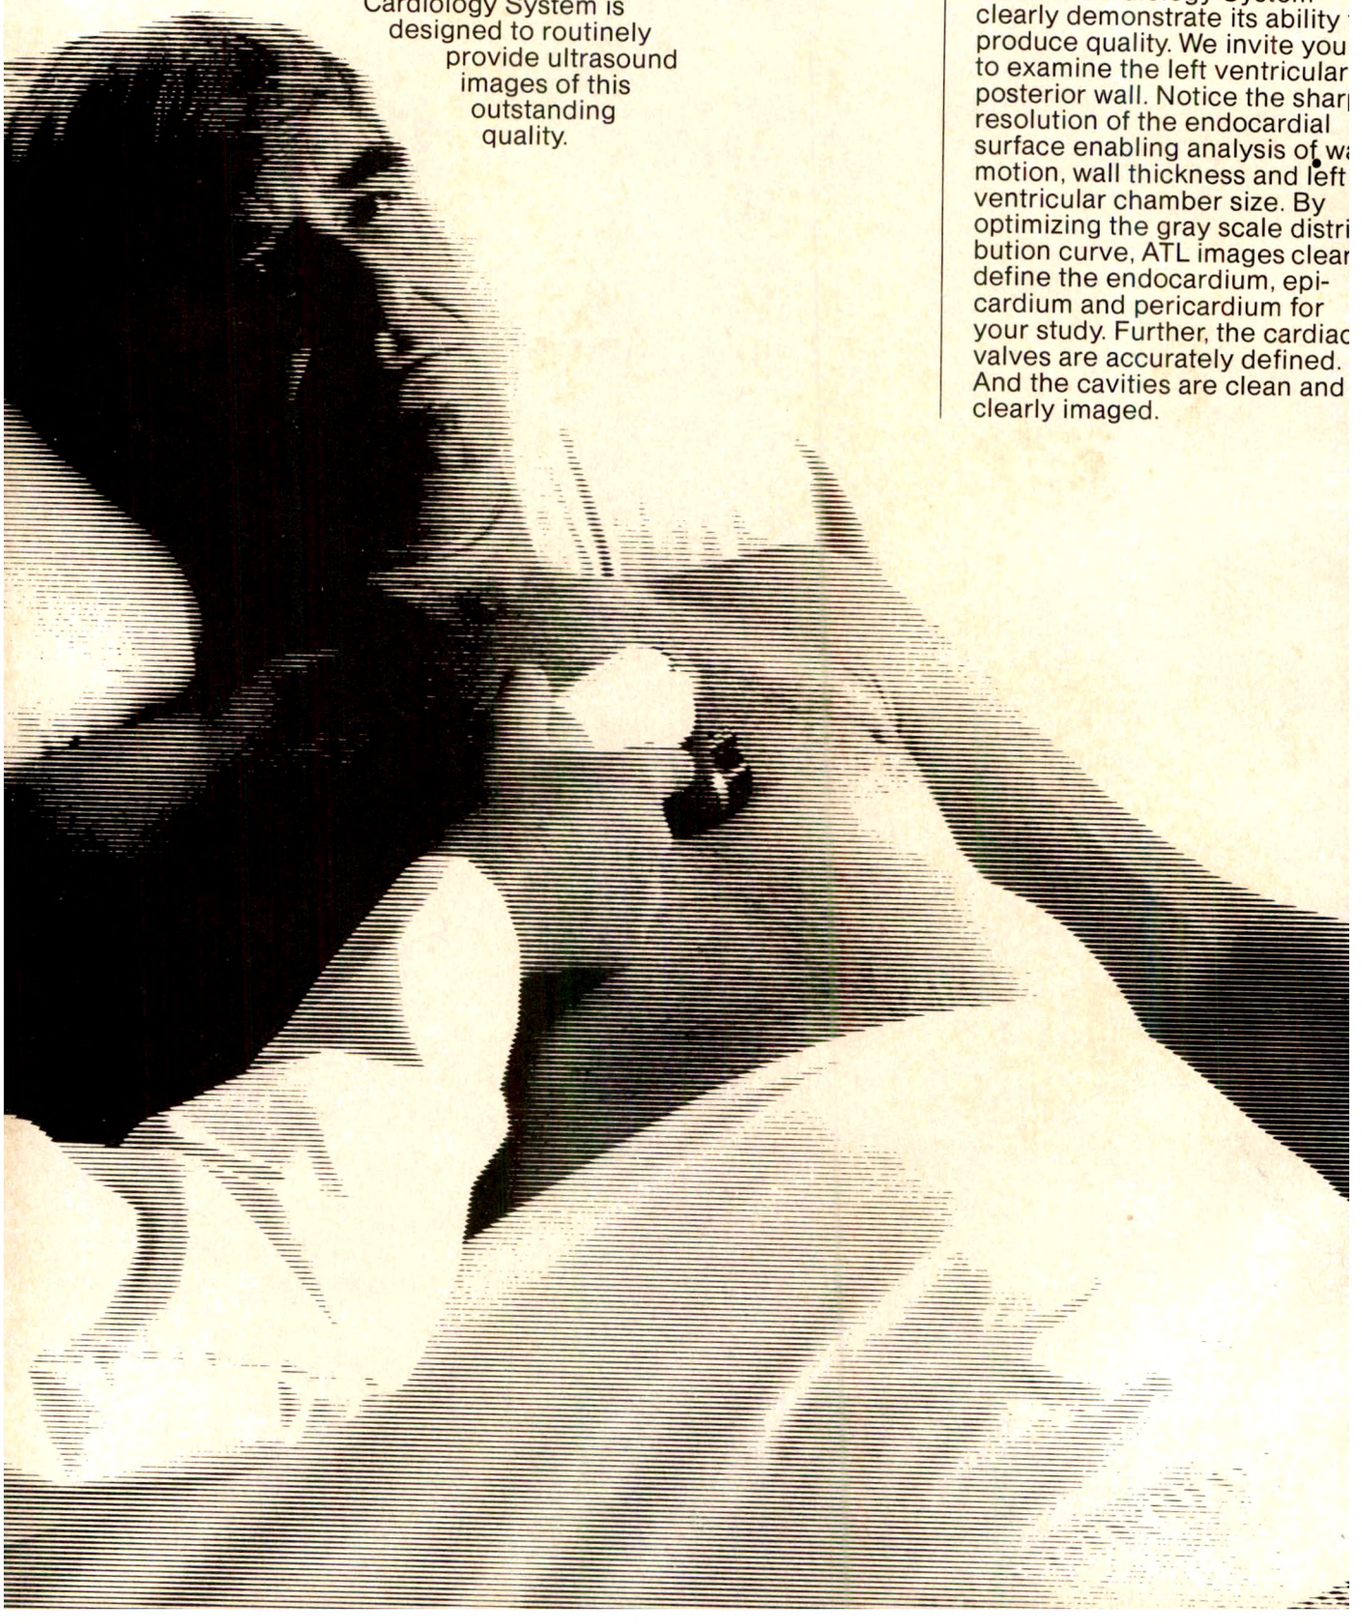
Patients presenting with signs and symptoms of TIA's should have a complete medical and neurologic evaluation. Consideration should be given to other disorders which resemble TIA's.

It is important to evaluate and treat, if appropriate, other diseases associated with TIA's and stroke such as hypertension and diabetes.

The recommended Bufferin® dosage for TIA is 1296 mg. a day (648 mg. twice a day or 324 mg. four times a day).

BUFFERIN: A BETTER WAY TO TAKE ASPIRIN WHEN LONG-TERM USE IS ADVISED

For full aspirin benefits, plus excellent gastric tolerance your patients deserve Bufferin: the daily dosage aspirin



For complimentary samples of Bufferin, please write: Bufferin, P.O. Box 65, Elizabeth, New Jersey 07207.

Composition: Each Bufferin tablet contains aspirin 324 mg. and the antacid Di-Alminate® (Bristol-Myers' brand of Aluminum Glycinate 48.6 mg. and Magnesium Carbonate 97.2 mg.). © 1980, Bristol-Myers Co.

BUFFERIN

Your diagnosis depends o

In noninvasive diagnosis, superior image quality provides the greatest assurance of rapid and reliable diagnosis, and maximum patient throughput. The ATL Mark III Cardiology System is designed to routinely provide ultrasound images of this outstanding quality.

Why are ATL images outstanding?

The images produced by the Mark III Cardiology System clearly demonstrate its ability produce quality. We invite you to examine the left ventricular posterior wall. Notice the shar resolution of the endocardial surface enabling analysis of wa motion, wall thickness and left ventricular chamber size. By optimizing the gray scale distri bution curve, ATL images clear define the endocardium, epi-cardium and pericardium for your study. Further, the cardiac valves are accurately defined. And the cavities are clean and clearly imaged.

superior image quality. ATL delivers.

A systems approach to clinical capabilities.

Although the Mark III Cardiology System produces ultrasound images of outstanding quality, its clinical capabilities don't stop there. The system is also modular with the capability of being upgraded by addition of pulsed Doppler flow detection. It is fully mobile for critical care examinations, and provides a choice of 3 MHz high resolution scan head for adult examinations or an optional 5 MHz scan head for neonatal use.

Because of its superb digital scan conversion, the Mark III Cardiology System offers both 2-D video format with an excellent freeze frame which is ECG-triggered and digital M-Mode. Also available is a new line scan recorder that makes excellent hard copy available for your records.

Consider the value/price/performance ratio.

When you compare image quality and other key benefits, you will find that the Mark III Cardiology System provides the most favorable value/price/performance ratio in the field. For complete technical details, please contact your local ATL representative or call or write

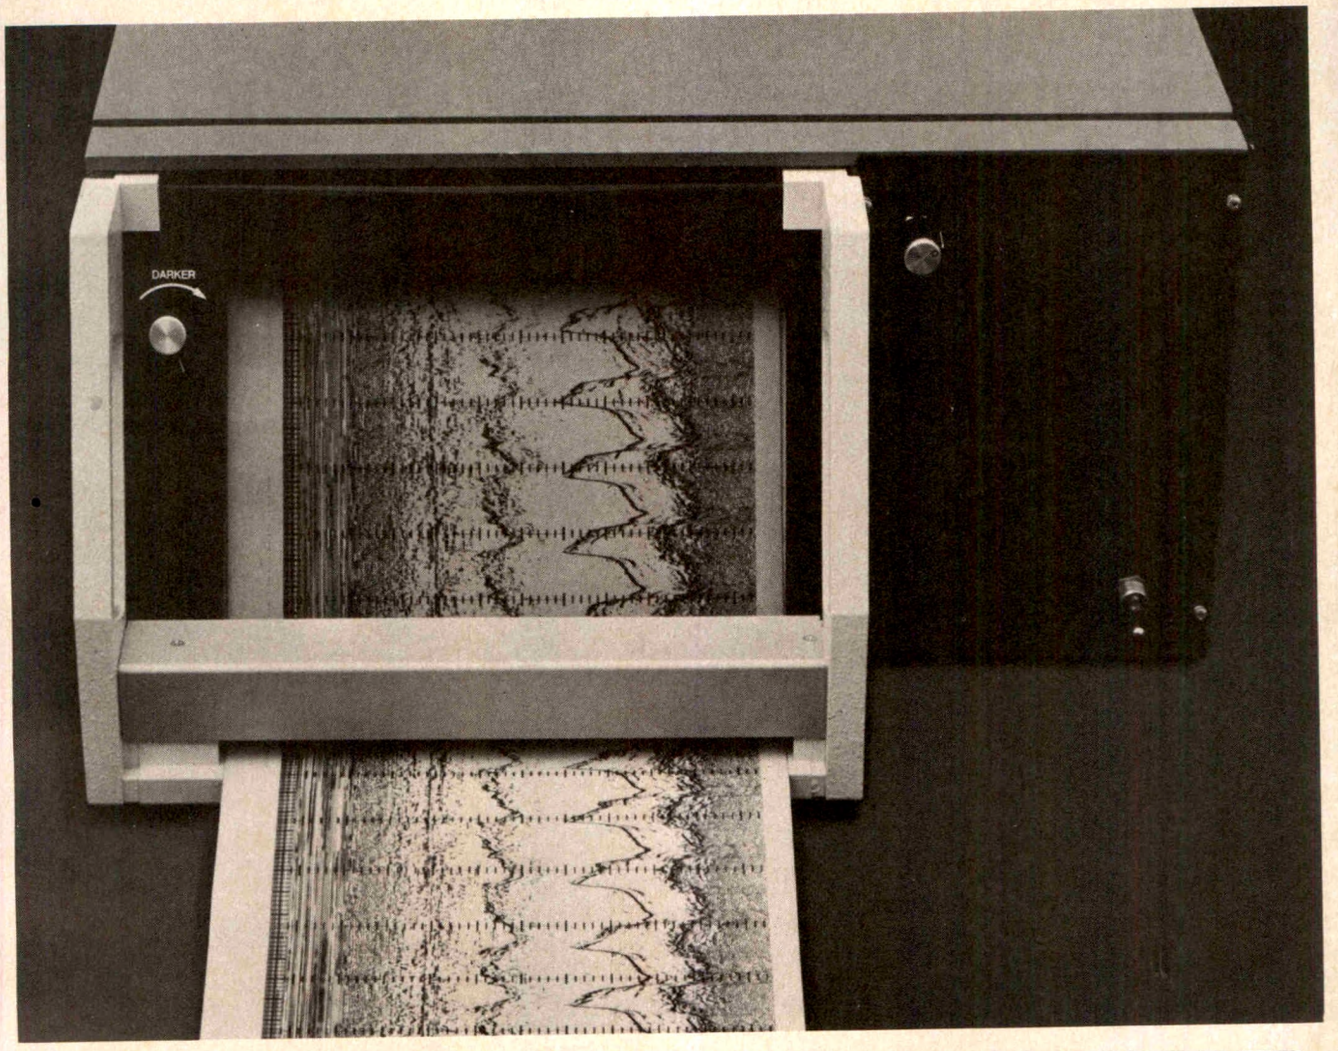
WE SEEK A CARDIOLOGIST

The 615-bed Immanuel Medical Center is seeking a board certified or board eligible cardiologist to practice in suburban Omaha. This attractive opportunity includes both private consultation and hospital non-invasive and invasive work, including open heart management. The successful candidate will be named Associate Director of the rapidly expanding, fully-equipped Department of Cardiology. A stable economy, fine schools, recreational opportunities and major universities welcome the qualified physician who chooses to practice in Omaha. **If interested, please contact Richard E. Collins, M.D., Director of Cardiology, (402) 571-1600, or Hans M. Link, President and Chief Executive Officer, Immanuel Medical Center, 6901 North 72nd Street, Omaha, NE 68122.**

Immanuel Medical Center is an all-new 615-bed health care complex including Hospital, Physical Medicine and Rehabilitation Center, Community Mental Health Center, Alcoholism Treatment Center, Nursing Home, Center for Continuing Education, Motel, and Physicians' Office Building.



Saffola® fights cholesterol better than any corn oil margarine.

LIMITED WARRANTY TO CONSUMERS
Good Housekeeping
PROMISES
REPLACEMENT OR REFUND IF DEFECTIVE

Higher in beneficial polyunsaturates. Contains no cholesterol. And tastes great.

Saffola is beneficial as part of a fat modified diet to help reduce serum cholesterol.

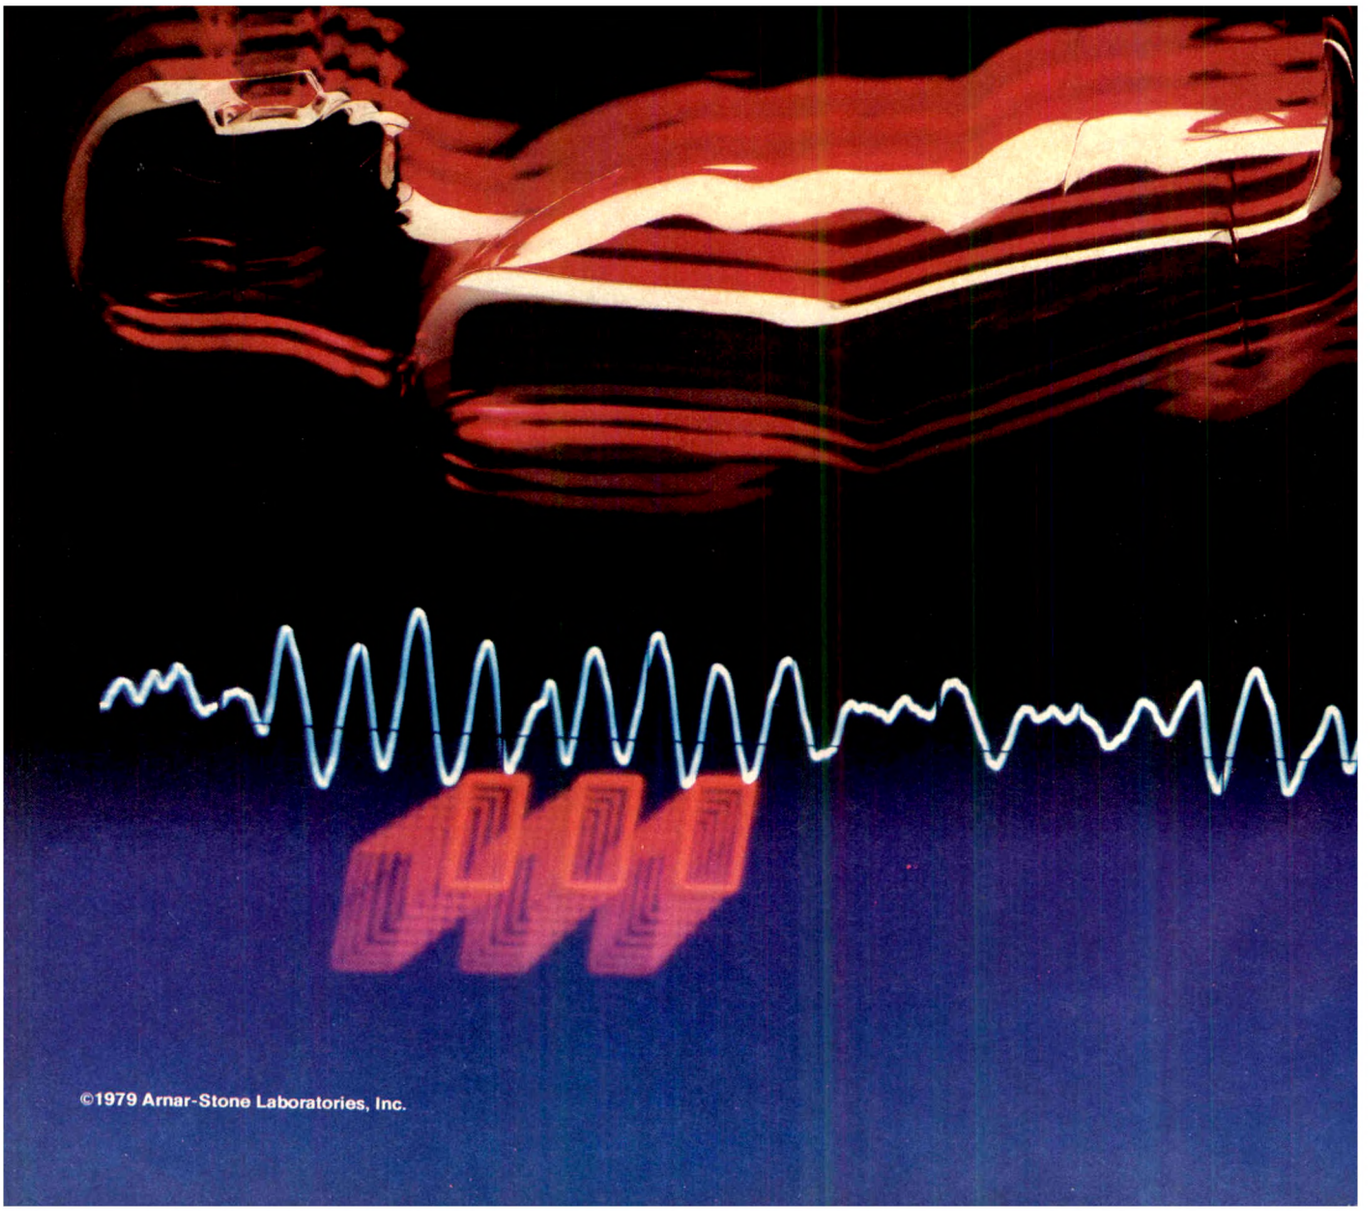
TAKE A LOOK AT HONEYWELL'S NEW RECORDER AND SEE WHAT YOU'VE BEEN MISSING IN ECHOCARDIOGRAMS.

If you're not seeing everything you expect from your present system, you should be looking at the LS-8—a totally new concept in presenting diagnostic information for echocardiography.

It delivers crisp black and white echocardiograms that won't fade. Echocardiograms that are developed dry, without chemicals, and without any warm-up delay caused by speed changes. So you get an instant echocardiogram for immediate evaluation.

And what an echocardiogram! Sharp and clear, with automatic intensity compensation for paper speeds from 5 to 100 mm/sec and the kind of high resolution and superior contrast that comes only from a wide and accurate gray scale range. Optional with direct print paper at 5 to 500 mm/sec.

Specific application modules provide optimum performance in a wide variety of applications, including M-mode echo, video for real time, and B-scan. Other modules can interface with up to six physiological data channels and provide timelines. The 2 kHz frequency response of the data channels provides diagnostic-quality phonocardiography recordings. And since the LS-8 is convection-cooled, there's no fan noise, no acoustical interference on sensitive phonocardiography channels.



Now add operation that's simpler than ever, a design that's quick and easy to service, and you have the LS-8, backed by the experience and expertise of people whose business is graphic recorder technology.

Honeywell's new LS-8 Stripchart Recorder will deliver every bit of image quality your ultrasound system is capable of. Ask your echo system supplier. Or contact Bob Shipman, Honeywell Test Instruments Division, Dept. AJC, Box 5227, Denver, Colorado 80217, phone 303/771-4700.

WE'LL SHOW YOU A BETTER WAY.

Honeywell

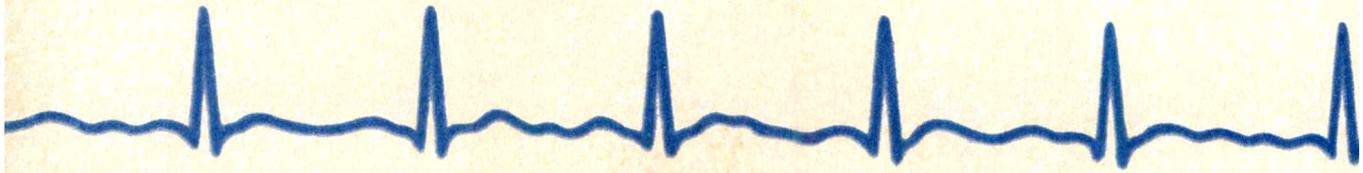
BRETYLOL®
(bretylium tosylate)

Unique antifibrillatory-antiarrhythmic effect
Unique mechanism of action
Unique safety: no cardiac depression



Bretylol® (bretylium tosylate), the unique new antifibrillatory-antiarrhythmic, provides lifesaving effects in the suppression of life-threatening ventricular arrhythmias unresponsive to lidocaine.

See last page of this advertisement for prescribing information.

BRETYLOL®
(bretylium tosylate):

Lifesaving potential in refractory ventricular arrhythmias

Unique antifibrillatory-antiarrhythmic effect

Studies in laboratory animals demonstrate that Bretylol significantly raises the ventricular fibrillation threshold with a consistency and magnitude that appears to be unique among antiarrhythmic agents.[1]

Bretylol (in conjunction with electrical cardioversion) frequently restores a normal sinus rhythm within minutes following intravenous injection in patients with ventricular fibrillation who have not responded to lidocaine.

Bretylol often controls ventricular tachycardia and other life-threatening ventricular ectopic rhythms, even when recurrent or refractory to lidocaine.

Clinically, Bretylol exhibits specific therapeutic effectiveness against refractory ventricular arrhythmias of various etiologies; for example, ventricular fibrillation and/or tachycardia associated with myocardial infarction,[2,6,9,10] open heart surgery,[7,8,10] and ischemic heart disease.[7] In one review of published experimental and clinical experiences with Bretylol,[11] the authors state, "clinical experience indicates that bretylium (Bretylol®) is frequently effective in the acute control of recurrent ventricular tachycardia or fibrillation resistant to other antiarrhythmic drugs... (and)...response of refractory ventricular arrhythmias to bretylium has been impressive."[11]

Unique safety

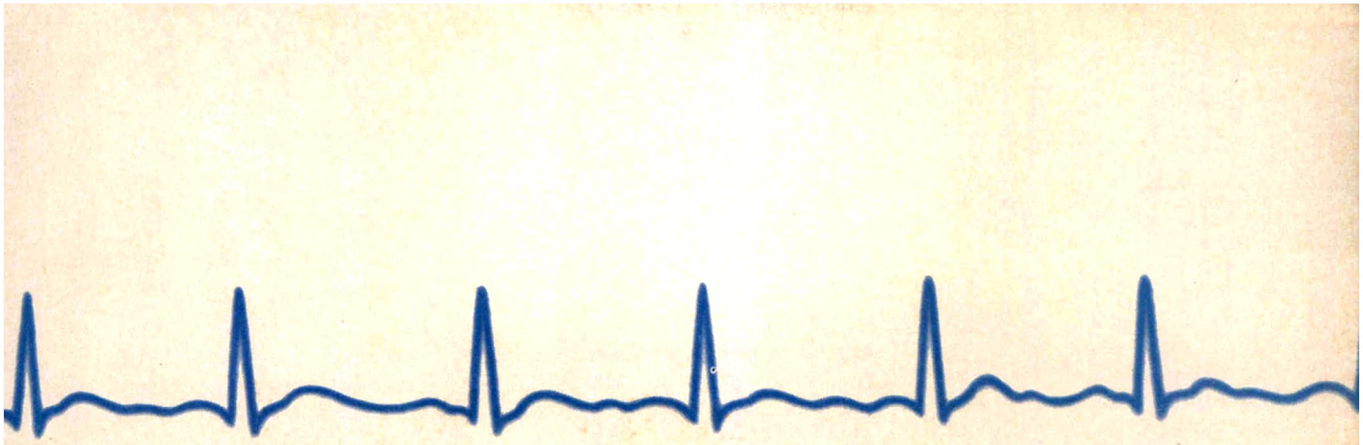
Unlike other antiarrhythmics, Bretylol does not depress cardiac function or exert a negative inotropic effect.[3]

There are no reports of Bretylol causing toxicity to any of the organs, including liver, kidney, heart, bone marrow, blood or central nervous system.

Therapy is generally well tolerated, and treatment is seldom discontinued because of adverse effects.

Reductions in blood pressure (usually orthostatic) may occur as a result of adrenergic blockade. If the patient is kept supine, the reduction in blood pressure is not usually clinically significant. Serious supine hypotension can occur in a few patients. Moreover, hypotension sometimes observed with Bretylol is not necessarily increased when the dosage is increased.

Unique cardiac effect



In laboratory studies Bretylol demonstrates a positive inotropic effect on the myocardium. Clinical reports confirm that Bretylol maintains cardiac output and does not depress myocardial function.[3]

Therefore, when used as an antiarrhythmic Bretylol should not interfere with the major therapeutic goal in the M.I. or post-open heart patient—the preservation of cardiac function.

It is recommended that the clinician consult the full prescribing information for dosage instructions and possible adverse effects prior to using Bretylol.

BRETYLOL® bretylium tosylate

Brief Summary of Prescribing Information

CLINICAL PHARMACOLOGY—BRETYLOL (bretylium tosylate) suppresses ventricular fibrillation and ventricular arrhythmias. The mechanisms of the antifibrillatory and antiarrhythmic actions of BRETYLOL are not established. In efforts to define these mechanisms, the following electrophysiologic actions of BRETYLOL have been demonstrated in animal experiments:

1. Increase in ventricular fibrillation threshold.
2. Increase in action potential duration and effective refractory period without changes in heart rate.
3. Little effect on the rate of rise or amplitude of the cardiac action potential (Phase 0) or in resting membrane potential (Phase 4) in normal myocardium. However, when cell injury slows the rate of rise, decreases amplitude, and lowers resting membrane potential, BRETYLOL restores these parameters toward normal.
4. Increase in impulse formation and spontaneous firing rate of pacemaker tissue as well as increased ventricular induction velocity.

The restoration of injured myocardial cell electrophysiology toward normal, as well as the increase of the action potential duration and effective refractory period without changing their ratio to each other, may be important factors in suppressing reentry of aberrant impulses and decreasing induced dispersion of local excitable states.

BRETYLOL has a positive inotropic effect on the myocardium, but it is not yet certain whether this effect is direct or is mediated by catecholamine release.

BRETYLOL is eliminated intact by the kidneys. In various studies of BRETYLOL excretion, estimates of the terminal half-life have varied from about 5 to about 10 hours, with an even wider range in individual subjects (4 to 17 hours). Whether this represents true intrapatient variability or limitations of methodology remains to be determined.

Effect on Heart Rate: There is sometimes an initial small increase in heart rate when BRETYLOL is administered, but this is an inconsistent and transient occurrence.

Hemodynamic Effects: Following intravenous administration of 5 mg/kg of BRETYLOL to patients with acute myocardial infarction, there was a mild increase in arterial pressure, followed by a modest decrease, remaining within normal limits throughout. Pulmonary artery pressures, pulmonary capillary wedge pressure, right atrial pressure, cardiac index, stroke volume index, and stroke work index were not significantly changed. These hemodynamic effects were not correlated with antiarrhythmic activity.

Onset of Action: Suppression of ventricular fibrillation is rapid, usually occurring within minutes following intravenous administration. Suppression of ventricular tachycardia and other ventricular arrhythmias develops more slowly, usually 20 minutes to 2 hours after parenteral administration.

INDICATIONS—BRETYLOL is indicated in the treatment of life-threatening ventricular arrhythmias, principally ventricular fibrillation and ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine or procainamide. At this time, BRETYLOL should not be considered a first-line antiarrhythmic agent.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrhythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS—There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS—Administration of BRETYLOL regularly results in postural hypotension. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL should be avoided.

In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY—The safety of BRETYLOL in human pregnancy has not been established.

USE IN CHILDREN—The safety and efficacy of this drug in children has not been established.

PRECAUTIONS—BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

Since BRETYLOL is excreted principally via the kidney, dosage should be reduced in patients with impaired renal function.

ADVERSE REACTIONS—Hypotension and postural hypotension have been the most frequently reported adverse reactions. Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route. Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

HOW SUPPLIED—NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP.

The Sell-Out Syndrome

'Never' is a long time and so that word probably shouldn't be used. But I'm tempted to say it in the face of so many other medical electronic firms selling out all around us. I cannot believe that money really means that much.

In 1965 I started Marquette Electronics in a funny old building that had 1600 square feet of space. I invested $7,500 and my partner another $7,500. Life was an unbelievable struggle. Designs didn't work, the customer didn't pay, the money ran short, and I worked fifteen hours a day. My partner continued with another business we had so we could both eat.

Today Marquette is $22 million in sales, 100,000 square feet of modern manufacturing facilities, some of the best researchers in the business, and world leadership in electrocardiography.

Every week someone contacts me to ask if we would sell out, be acquired, merge or otherwise mess up our beautiful world of success. People suggest absolutely wild prices, unbelievable benefits, and infer that if we won't budge, we'll be destroyed by the 'giants'.

Every month some company like ours is sold for those fancy prices to some overly profitable giant, and everyday I hear of the horrors from the guys who stick around for the bureaucratic onslaught. Everyday I hear how the good old Yankee entrepreneurial spirit is broken into millions of pieces by a conglomerate without spirit, heart or even an ability to get things done.

Of course there are special circumstances that might necessitate a sell-out. The key guy dies. Some bad luck drains the financial resources dry. A competitor strikes a tough blow or the government legislates you to your knees. And, yes, I know I can't be the chief executive forever, but does that mean we must sell out and destroy what we have struggled to build over the most productive years of our lives?

These would be buyers tell me we need more money to keep up with research. Hog wash! I can't pump money into our Engineering Department of brilliant guys to make them invent or develop faster. We always seem to be ahead of our competition in innovation anyway, so how can more money make it happen better or faster?

They say we'll need money for continued growth. But our profits provide for our growth, and we grow 25-35% a year and make sure to stay profitable so our bankers loan us the needed operating capital. They said we'd need money for new facilities, yet our beautiful 100,000 square foot plant was entirely financed by an industrial bond issue.

So what, then, are the alternatives? Just keep growing and going forever? We all get old in the end and we must make room for the young if we wish to perpetuate our company and what it stands for. If we have kids that want to step in, that's fine, but they have to want to and they have to be every bit as talented and ambitious as anyone else.

Our government has worked hard for many years to make the transfer of ownership in a company like ours to our young talent almost impossible. They have set capital gain taxes, gift taxes, income taxes and miscellaneous taxes of all kinds such that it's easy to go broke or go to jail if you ever get such a dumb idea, but we're going to try anyway. We're going to set our course for the next ten years so that we let the young, talented, capable guys in our company become major stockholders. And the stock will come from us...the old timers who must step back and have faith that someone else can carry on the work we're doing to advance the science of electrocardiography.

Someday I may regret writing these words. Someday I may wish we didn't turn our backs on those big, juicy offer from the conglomerates, but I don't think so. And in these words may be a lesson to others about what made this country and its industry great in the first place — and it surely wasn't going part way and then selling out to a devouring giant for the sake of money.

Sincerely,
Michael J. Cudahy
President

Vagal Techniques for Termination of Paroxysmal Supraventricular Tachycardia

MENASHE B. WAXMAN, MD
ROBERT W. WALD, MD
ARJUN D. SHARMA, MD
FELIX HUERTA, MD
DOUGLAS A. CAMERON, MD

Toronto, Ontario, Canada

Maneuvers that reflexly increase vagal tone were deployed to terminate the tachycardia in 68 consecutive patients with paroxysmal supraventricular tachycardia. The order and success rate of the protocol was as follows: 57 episodes were terminated with carotid sinus pressure alone or after pretreatment with edrophonium, 5 were terminated with the Valsalva maneuvers and 6 were terminated with phenylephrine. Potency testing showed that phenylephrine evoked the greatest increase in vagal tone. All cases demonstrated slowing of tachycardia ranging from 40 to 220 ms ± standard error of the mean (mean 79.0 ± 3.8 ms) followed by abrupt termination. Pauses after termination ranged from 900 to 3,300 ms (mean 1,683.8 ± 66.6) with 54 patients showing pauses of 2,000 ms or less. Termination was highly reproducible showing an overall success of 148 (92 percent) of 160 trials among 22 selected cases. The extent of increased vagal tone needed to terminate paroxysmal supraventricular tachycardia was raised by augmented sympathetic tone (infusion of isoproterenol) and decreased by reduced sympathetic tone (pretreatment with propranolol). Thus, paroxysmal supraventricular tachycardia can be rapidly, safely and consistently terminated by maneuvers that reflexly increase vagal tone.

Maneuvers that increase vagal tone have been used to terminate paroxysmal supraventricular tachycardia since at least 1913 and have gained wide acceptance.[1–14] Termination of tachycardia by an increase in vagal tone not only is immediate but also may be a specific test for paroxysmal supraventricular tachycardia[1,4,15] In contrast, other supraventricular tachycardias such as sinus or ectopic atrial tachycardia, atrial flutter or atrial fibrillation usually show transient slowing of the ventricular rate, whereas ventricular tachycardia with rare exceptions shows no response to increased cardiac vagal tone.[4,7,15–17] In this study we report our experience in terminating 68 consecutive cases of paroxysmal supraventricular tachycardia by a select group of maneuvers that reflexly enhance vagal tone

This study was performed with several objectives in mind: (1) to establish prospectively the success rate with which a fixed protocol of common vagal maneuvers terminates paroxysmal supraventricular tachycardia; (2) to assess the reproducibility of various vagal maneuvers to terminate such tachycardia; (3) to measure the relative potency of different vagal techniques to terminate such tachycardia; (4) to examine the behavior of such tachycardia preceding its termination with vagal maneuvers; (5) to establish the safety of these interventions; and (6) to measure the effects of altered sympathetic activity on the potency of the vagal maneuvers used to terminate the tachycardia.

From the Department of Medicine, University of Toronto Faculty of Medicine and Division of Cardiology of the Toronto General Hospital, Toronto, Ontario, Canada, This work was supported in part by grants from the Ontario Heart Foundation, Toronto and the Canadian Heart Foundation, Ottawa, Ontario, Canada. Manuscript received December 18, 1979; revised manuscript received March 3, 1980, accepted April 10, 1980.

Address for reprints: Menashe B. Waxman, MD, Cardiovascular Unit, Toronto General Hospital, 101 College Street, Toronto, Ontario, Canada, M5G 1L7.

Methods

Study Patients

Sixty-eight consecutive patients with recurrent paroxysmal supraventricular tachycardia were studied during spontaneous or induced episodes of tachycardia at the Toronto General Hospital between 1972 and 1976. The patients ranged in age from 14 to 74 (mean 42) years. The clinical cardiac diagnosis in the 68 patients was no cardiac disease (51 patients,) coronary artery disease (5), rheumatic valve disease (6), mitral valve prolapse (3) and Ebstein's anomaly of the tricuspid valve (3). Thirty-three patients (group A) were seen in the Emergency Department with established paroxysmal supraventricular tachycardia because the attending physicians there were unable to terminate the arrhythmia by maneuvers that increased vagal tone. In these patients there was generally only one opportunity to terminate the tachycardia unless a second episode started spontaneously. Of these patients, two were receiving oral digoxin (0.25 mg daily), three were receiving propranolol (40 to 160 mg daily) and one was receiving quinidine sulfate (800 mg daily). Thirty-five patients (group B) were referred electively for electrophysiologic studies because they had had for many years recurrent long-lasting attacks that posed diagnostic and therapeutic problems. In these patients all drugs were discontinued at least 3 days before the studies. During electrophysiologic studies multiple episodes of paroxysmal supraventricular tachycardia were induced and terminated.

Features of the tachycardia: In all patients the features of the tachycardia met criteria that suggested it involved or was confined to the atrioventricular (A-V) node.[18–22] The characteristics of the attacks were: (1) sudden onset and sudden offset; (2) the QRS configuration during the tachycardia was identical to that during sinus rhythm except for cases with rate-related aberration or cases with overt Wolff-Parkinson-White preexcitation syndrome. In the latter group the QRS configuration during tachycardia was either normalized and identical to His bundle escape beats or aberrant in a rate-related manner[15,23,24]; (3) the heart rate ranged from 140 to 220 beats/min; (4) the atria and ventricles were always fixed in a 1:1 ratio; and (5) surface P waves either were not seen because they were inscribed simultaneously with the QRS complexes or, when seen, were confined to the proximal portion of the S-T segment.

Patients in group B (35 cases) underwent electrophysiologic studies and the following additional criteria suggested that the A-V node participated in the tachycardia: (1) the attacks could easily be initiated by single early premature atrial stimuli that conducted with a critically prolonged A-V nodal conduction time[25]; (2) attacks could be terminated by a single well timed atrial stimulus[25,26]; (3) atrial electrograms showed that atrial depolarization in all cases occurred either coincident with the QRS complex or within the proximal portions of the S-T segment and the direction of depolarization was always retrograde[21,27–30]; and (4) a His bundle potential preceded the QRS complexes with an H-V interval range of 40 to 55 ms.

These cases could be further subdivided into those that involved an overt or concealed lateral accessory A-V pathway and those that did not.[20,28] Participation of a lateral accessory A-V pathway (overt or concealed) in the tachycardia circuit was based on the following two criteria: (1) Eccentric retrograde atrial activation sequence followed each QRS complex during tachycardia,[29,30] and (2) spontaneous disappearance of functional bundle branch block during the tachycardia was accompanied by simultaneous acceleration of the tachycardia that was traceable to a reduced ventriculoatrial interval.[31–33] Of the 35 patients in group B, the tachycardia circuit was confined to the A-V node in 12 and involved a bypass tract in 23.

Study Protocols Pertinent to all Patients

Order of vagal maneuvers: In all 68 patients termination of tachycardia was attempted by one of us (M.B.W.) in the following consistent order: (1) single applications of left or right carotid sinus pressure; (2) multiple applications of unilateral carotid sinus pressure; (3) carotid sinus pressure after pretreatment with the anticholinesterase edrophonium hydrochloride (Tensilon®), 5 to 10 mg intravenously; (4) Valsalva maneuver; (5) Valsalva maneuver after pretreatment with edrophonium, 5 to 10 mg intravenously; and (6) phenylephrine, 0.1 to 1.0 mg intravenously. In each case the protocol was pursued until the tachycardia was terminated. This meant that the different methods were not tried with equal frequency during the performance of the initial protocol. For example, carotid sinus pressure was tried in all 68 patients whereas phenylephrine, the last intervention in the sequence, was tried in only 6 patients after all previous maneuvers had failed. In all subsequent studies the patients were categorized by the vagal maneuver that first terminated the tachycardia during this initial protocol.

The interval between the last QRS complex of the tachycardia and the first subsequent sinus conducted complex was measured to the nearest 50 ms interval. When several terminations were performed in a particular patient, the arithmetic mean of the pauses was used. Slowing of tachycardia before termination was determined by measuring the prolongation in cycle length from the control value to the last cycle of the tachycardia to the nearest 10 ms using high speed or magnified tracings. When several terminations were analyzed in the same patient, the arithmetic mean of these determinations was used.

Techniques of vagal maneuvers: In all patients, carotid sinus pressure was applied in a standard manner.[1,34] With the patient supine and the head hyperextended, the sinus (right or left) was compressed for 1 to 5 seconds using steady pressure rather than massage because the former is more reproducible in our hands. Valsalva maneuvers in patients in group A were not quantitated and consisted of a maximal strain held for 10 seconds. During Valsalva maneuvers performed by patients in group B, oral pressure was displayed on a manometer in full view of the patient, who was asked to maintain a constant pressure of 30 to 60 mm Hg for 5 to 10 seconds.[35] To prevent the patient from closing the glottis and generating oral pressure only, a small leak was introduced into the system. This obliged the patient to keep the glottis open during the strain phase, thus equilibrating intrathoracic and oral pressures.[35] Edrophonium hydrochloride, 5 or 10 mg, was administered as an intravenous bolus dose and either carotid sinus pressure or a Valsalva maneuver was performed 30 seconds later, at a time when the patient subjectively experienced some of the muscarinic and nicotinic actions of this drug.[5] Phenylephrine was administered as repeated intravenous bolus injections starting with 0.1 mg and increasing this dose in increments of 0.1 to 0.2 mg. The maximal dose administered was limited by the peak systolic pressure not being allowed to exceed 180 mm Hg. Blood pressure was measured at 15 second intervals in patients in group A and continuously in group B patients using an intraarterial line. After each dose of phenylephrine sufficient time was allowed to elapse for the blood pressure to return to the control value before the subsequent dose was administered.

Study Protocols in Patients in Group B

Electrophysiologic studies: The 35 patients in group B underwent intracardiac electrophysiologic studies. His bundle electrograms, high and low right atrial electrograms and low left atrial electrograms (recorded either from a catheter introduced into the left atrium through a probe-patent foramen ovale or from the distal coronary sinus) were monitored. The sequence of atrial activation was determined during the tachycardia and compared with that during sinus rhythm.[28–30] The right atrium was paced using right atrial pacing electrodes. Paroxysms of supraventricular tachycardia were initiated by scanning the entire diastole at intervals of 5 to 10 ms first with a single, then (if necessary) with multiple atrial stimuli.[36] Once supraventricular tachycardia was induced it was allowed to stabilize for 5 minutes, and at this point the protocol for termination was begun. During these studies the surface electrocardiogram, beat to beat heart rate, intraarterial blood pressure and oral pressure generated during the Valsalva maneuver were continuously recorded.

Reproducibility studies: To study the reproducibility of tachycardia termination with each vagal intervention, numerous episodes were induced in 22 selected patients. The following protocols were carried out: (1) single applications of carotid sinus pressure to terminate 10 episodes of paroxysmal supraventricular tachycardia in each of 10 patients (100 trials); (2) single applications of carotid sinus pressure to terminate 5 episodes of tachycardia in each of 5 patients after pretreatment with edrophonium hydrochloride, 10 mg intravenously (25 trials); (3) Valsalva maneuvers (40 mm Hg strain for 10 seconds) to terminate 5 episodes of tachycardia in each of 3 patients (15 trials); and (4) phenylephrine (minimal dose) to terminate 5 episodes of tachycardia in each of 4 patients (20 trials). Whenever a given episode failed to terminate with a particular intervention, the intervention was counted as a failure and the tachycardia was terminated with atrial pacing. In the patients undergoing these trials the tachycardia had originally been converted with the intervention being tried.

Potency studies: The relative potency of different vagal maneuvers was determined by finding and comparing the minimal dose of phenylephrine and corresponding pressor effect needed to terminate paroxysmal supraventricular tachycardia in (1) 15 patients whose tachycardia terminated with a single application of carotid sinus pressure; (2) 9 patients whose tachycardia terminated with carotid sinus pressure after administration of edrophonium; (3) 3 patients whose tachycardia terminated with a Valsalva maneuver; and (4) 4 patients whose tachycardia terminated only after administration of phenylephrine.

Effects of background sympathetic activity: Eight patients from group B were examined under various conditions of sympathetic activity. Four patients who responded to carotid sinus pressure and four who responded only to phenylephrine were selected. In the first four the rate of the tachycardia and the minimal dose of edrophonium needed to terminate it was determined during control conditions and after attainment of a new steady state with an isoproterenol infusion (2 μg/min intravenously). Edrophonium, used because it is a relatively pure vagal stimulant,[5,6] was administered as intravenous bolus injections in sequentially increasing doses of 5, 10, 15 and 20 mg until the tachycardia terminated. Sufficient time was allowed between consecutive doses to allow the heart rate to return to the control level and any subjective symptoms to disappear. In the four patients who required phenylephrine for termination of tachycardia, the minimal dose of phenylephrine required to terminate supraventricular tachycardia before and 10 minutes after partial beta adrenergic blockade with propranolol (0.07 mg/kg intravenously) was determined.

Effects of parasympathetic blockade: Eight other patients from group B were examined before and after partial vagal blockade with atropine, 1.2 mg intravenously. Four of these patients were from among those whose tachycardia terminated with carotid sinus pressure, two had responded to a Valsalva maneuver and two to phenylephrine. Termination of tachycardia by these maneuvers was documented and then retested 5 minutes after administration of atropine, 1.2 mg intravenously.

The purpose and methods of study were carefully explained and verbal and written consent were obtained from each participant.

Results

Overall response: The success rate of the various vagal maneuvers in terminating paroxysmal supraventricular tachycardia is shown in Figure 1. Tachycardias in all 68 patients could be terminated by the protocol. Among the 68 patients, the tachycardia responded to a single application of carotid sinus pressure in 25 and to multiple applications of carotid sinus

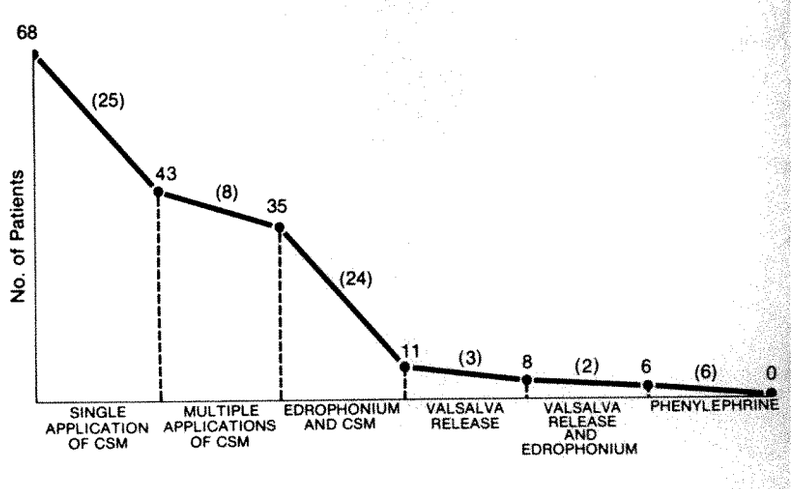

FIGURE 1. Success rate of termination of paroxysmal supraventricular tachycardia by different vagal maneuvers. The order of interventions along the abscissa corresponds to the protocol followed. The initial figure represents the number of patients submitted to any particular maneuver, and the figure in parentheses denotes the number whose tachycardia was terminated by each respective maneuver. For example, in 25 of 68 patients, tachycardia was terminated by a single application of carotid sinus massage (CSM) or pressure. In 57 of the 68, the tachycardia was terminated by single or multiple applications of carotid sinus pressure with or without edrophonium. In 5 of 11 patients the tachycardia responded to a Valsalva maneuver with or without edrophonium. In six of six patients the tachycardia was terminated with phenylephrine.

pressure in an additional 8. Among the remaining 35 patients, 24 episodes of tachycardia were terminated by carotid sinus pressure applied after pretreatment with edrophonium, 5 to 10 mg. Thus, in 57 of 68 patients, paroxysmal supraventricular tachycardia was terminated by carotid sinus pressure with or without injection of edrophonium. Carotid sinus pressure caused a decrease in arterial blood pressure that provided a semiquantitative measure of the extent and duration of the application.[37–39] After edrophonium, the extent of carotid sinus pressure needed to terminate paroxysmal supraventricular tachycardia as judged by the degree and duration of decrease in blood pressure was considerably less than that during the original application of carotid sinus pressure that failed to terminate the tachycardia (Fig. 2).

Among the remaining 11 patients who did not respond to carotid sinus pressure, the tachycardia was terminated by Valsalva maneuvers in 5 patients several seconds after release of the strain and coincident with the hypertensive phase (Fig. 3). Three of the six patients whose tachycardia could not be terminated by a Valsalva maneuver were in group A, and we were thus unable to determine the reason for failure; the other three patients could not maintain a strain above 22 mm Hg and thus an insufficient overshoot in blood pressure was produced. Phenylephrine in doses ranging from 0.1 to 0.6 mg terminated paroxysmal supraventricular tachycardia in all six remaining patients (Fig. 4).

Reproducibility of termination of paroxysmal supraventricular tachycardia: Once a specific vagal maneuver was found to terminate paroxysmal supraventricular tachycardia successfully in a particular patient, this observation was subsequently demonstrated to be highly reproducible. A single application of carotid sinus pressure terminated 92 (92 percent) of 100 episodes of tachycardia in 10 patients; 24 (96 percent) of 25 episodes after pretreatment with edrophonium in 5 patients; a Valsalva maneuver terminated 12 (80 percent) of 15 episodes in 3 patients; and phenylephrine terminated 20 (100 percent) of 20 episodes of in 4 patients. The overall success rate was 147 (92 percent) of 160 trials.

Relative potency of different vagal techniques: Use of the amount of phenylephrine and the pressor response as a measure of the degree of vagal stimulation required to terminate the tachycardia revealed significant differences among the various patient groups identified with the initial protocol (Fig. 5). Fifteen patients who originally responded to a single application of carotid sinus pressure required a mean dose of phenylephrine of 0.15 ± 0.02 mg to terminate their tachycardia; nine patients whose tachycardia terminated with carotid sinus pressure and edrophonium required a mean dose of 0.26 ± 0.02 mg of phenylephrine; three who responded to a Valsalva maneuver required a mean dose of 0.42 ± 0.04 mg of phenylephrine; and four who responded only to phenylephrine required an average dose of 0.50 ± 0.07 mg of the drug to stop the tachycardia. The corresponding average pressor responses were 16.8 ± 0.7, 26.1 ± 1.7, 36.7 ± 1.7 and 56.3 ± 5.0 mm Hg, respectively.

Behavior of paroxysmal supraventricular tachycardia before termination: In all patients, paroxysmal supraventricular tachycardia always exhibited some slowing before termination and then

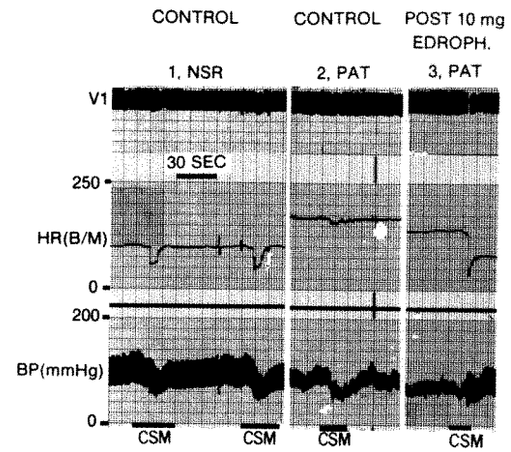

FIGURE 2. Case 1. Lead V_1, beat to beat heart rate (HR) in beats/min (B/M) and blood pressure (BP) in mm Hg, recorded during normal sinus rhythm (NSR) (**left panel**) and during supraventricular tachycardia (PAT) (**middle** and **right panels**). The extent and duration of carotid sinus massage (CSM) or pressure in each panel could be assessed semiquantitatively by the degree of reduction in blood pressure. During sinus rhythm, carotid sinus pressure decreased blood pressure and transiently slowed the rate of tachycardia. During control conditions, supraventricular tachycardia (**middle panel**) was not terminated with carotid sinus pressure alone. A vigorous application of carotid sinus pressure decreased blood pressure considerably and transiently slowed, but did not end, the tachycardia. After pretreatment with 10 mg of edrophonium (EDROPH) (**right panel**), the rate of tachycardia was slower. A smaller application of carotid sinus pressure again lowered blood pressure, slowed the tachycardia and restored sinus rhythm.

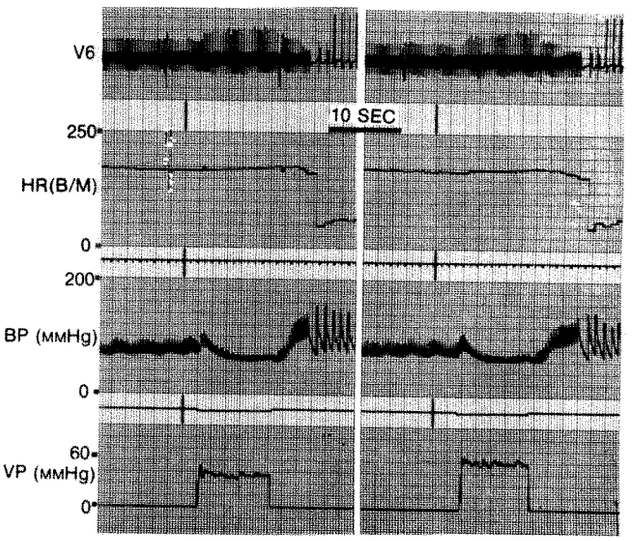

FIGURE 3. Case 2. Lead V_6, beat to beat heart rate (HR), blood pressure (BP) and Valsalva pressure (VP) recorded during two consecutive episodes of supraventricular tachycardia. The **left** and **right** panels show Valsalva pressures of 40 and 60 mm Hg, respectively. During the strain the peak and pulse pressure decreased. Several seconds after release of the strain, blood pressure rose above control level, the tachycardia slowed and then terminated.

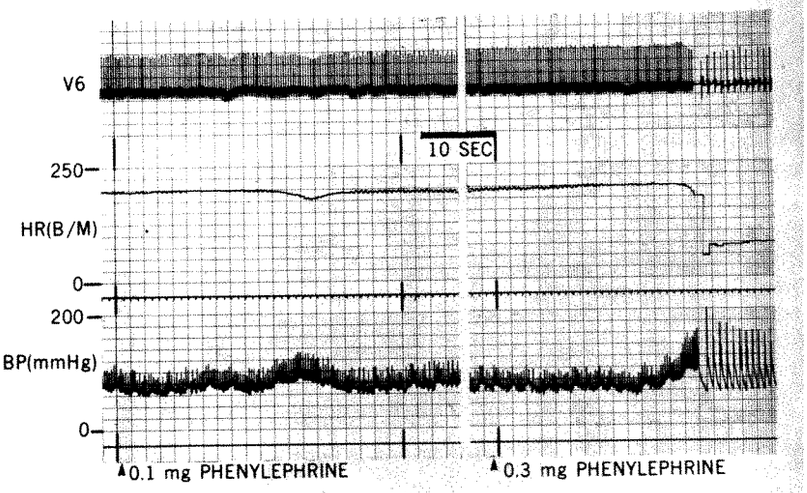

FIGURE 4. Case 3. Recordings of lead V_6, beat to beat heart rate (HR) and blood pressure (BP) during an episode of supraventricular tachycardia. **Left panel,** after administration of 0.1 mg of phenylephrine, the blood pressure increased and the tachycardia slowed transiently but did not terminate. **Right panel,** after administration of 0.3 mg of phenylephrine, the blood pressure was sufficiently increased to slow and stop the tachycardia.

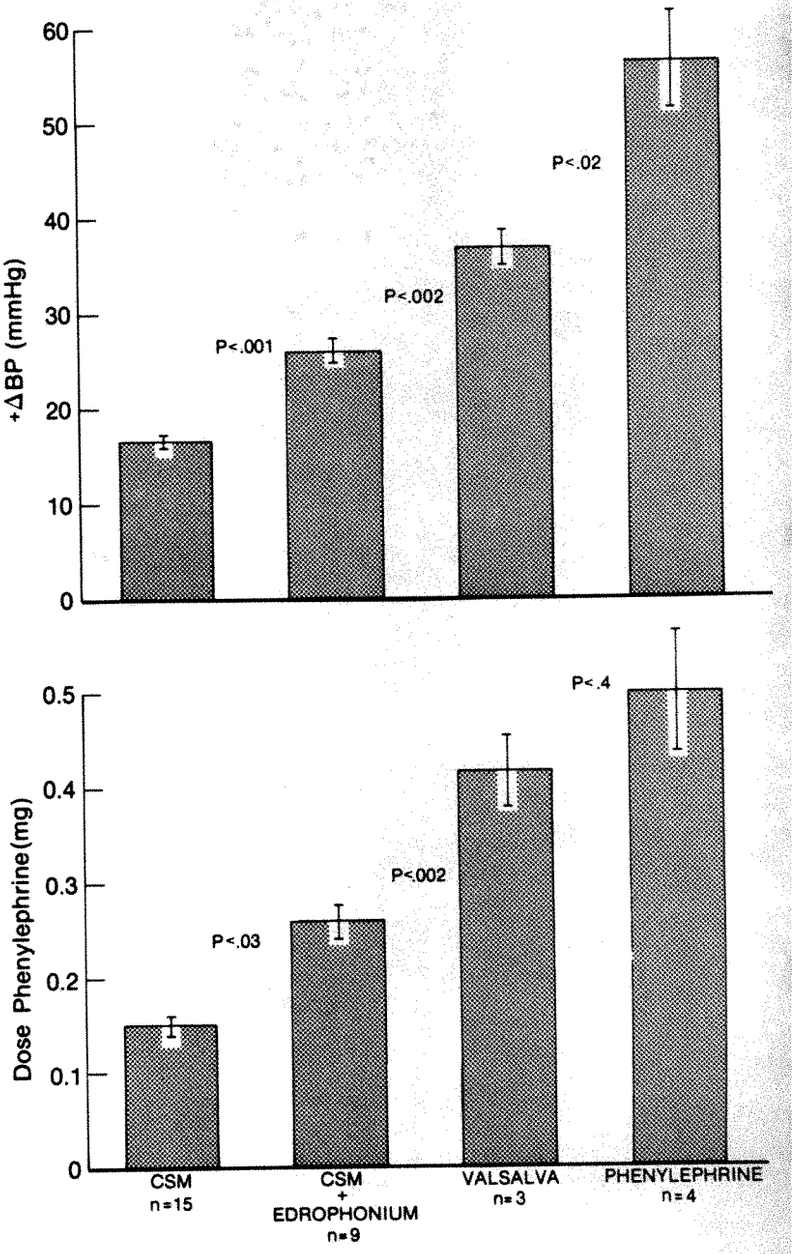

FIGURE 5. Comparison of the dose of phenylephrine and pressure response needed to terminate paroxysmal supraventricular tachycardia among the different patient groups. Patients who responded to a single application of carotid sinus massage (CSM) (pressure) required the smallest dose of phenylephrine for termination; those in the phenylephrine group required the largest dose and pressor response. Unlike the pressor difference between the Valsalva and phenylephrine groups, the difference in dose of phenylephrine in the two groups was not statistically significant. n = numbers of patients; p = probability.

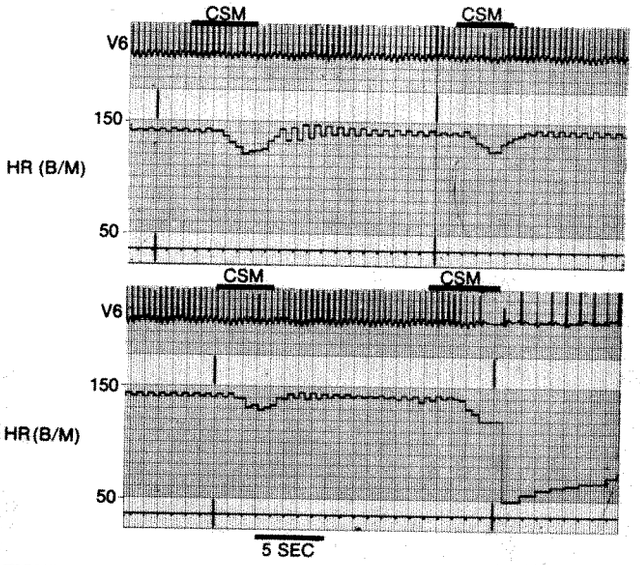

FIGURE 6. Case 4. Lead V_6 and beat to beat heart rate (HR) recorded during an episode of supraventricular tachycardia. Four applications of carotid sinus massage (CSM) (pressure) are shown. The first three applications produced slowing without termination and the tachycardia resumed its control rate in several seconds. The fourth application finally terminated the tachycardia.

abruptly converted to sinus rhythm (Fig. 6). The slowing ranged from prolongation of the cycle length by 40 to 220 ms (mean 79.7 ± 3.8). In 8 patients the cycle length was prolonged by more than 100 ms while 60 showed cycle length prolongation of 100 ms or less. Transient slowing was also seen when vagal maneuvers failed to terminate the tachycardia (Fig. 2 and 6). Slowing of tachycardia coincided with (1) the hypotensive phase during carotid sinus massage (Fig. 2), (2) the onset of hypertension after release of the Valsalva strain (Fig. 3) and (3) the onset of hypertension after phenylephrine (Fig. 4). In all but one patient, the tachycardias consistently stopped without passing through a phase of anterograde or retrograde block. In one exception, a patient whose tachycardia was confined to the A-V node, occasional episodes of tachycardia terminated by vagal maneuvers passed through a phase of A-V block before conversion (Fig. 7, bottom), although most episodes did not (Fig. 7, top).

Termination of paroxysmal supraventricular tachycardia with aberrant conduction: Two of the 68 patients had permanent left bundle branch block and in both the QRS configuration was identical during sinus rhythm and during paroxysmal supraventricular tachycardia. In eight patients, rate-related right (three patients) or left (five patients) bundle branch block was present during paroxysmal supraventricular tachycardia. In each of these, termination of the tachycardia by an increase in vagal tone slowed the tachycardia sufficiently to eliminate the rate-related bundle branch block for one or more cycles before termination (Fig. 8), provided the maneuver was not applied too abruptly.

Pause after termination of paroxysmal supraventricular tachycardia: The pause after termination of tachycardia ranged from 900 to 3,300 ms (mean 1683 ± 66.6). In 55 patients the pause was 2,000 ms or less and in 13 it exceeded 2,000 ms. In three patients the pause was greater than 3,000 ms, the longest pause being 3,300 ms. There were no secondary pauses that exceeded the initial pause.

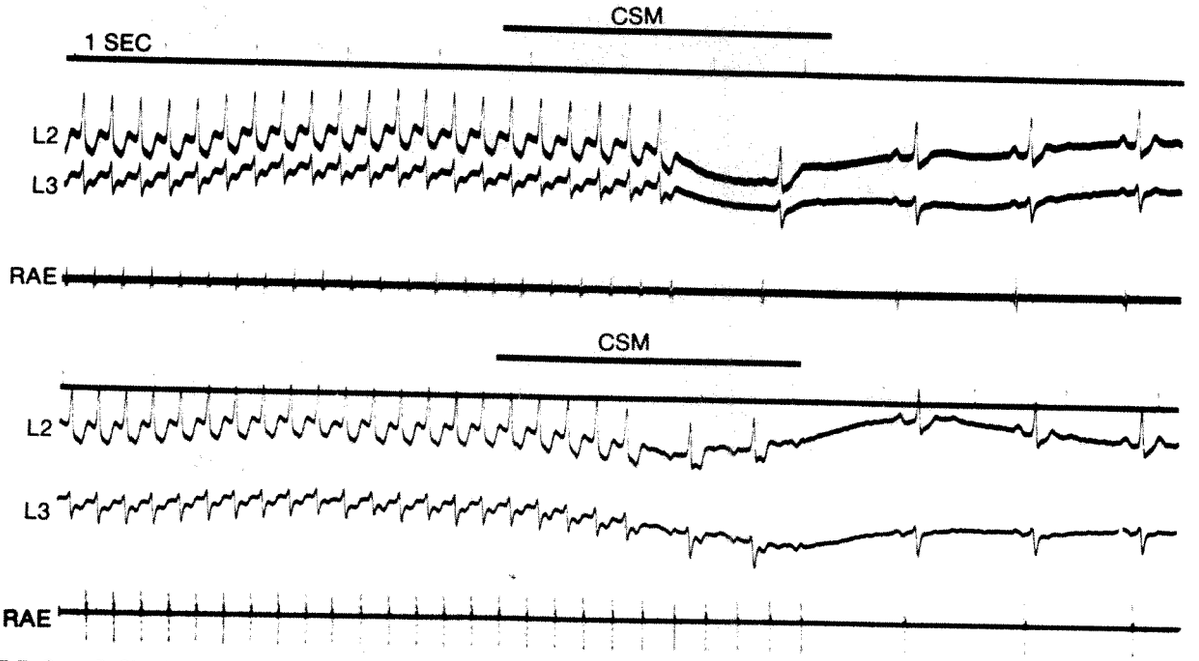

FIGURE 7. Case 5. Simultaneous recording of leads II (L2) and III (L3) and a right atrial electrogram (RAE). The first episode of tachycardia (**top**) is terminated by carotid sinus massage (CSM) (pressure) without passing through a phase of antecedent atrioventricular block. The second episode of tachycardia (**bottom**) is terminated by carotid sinus pressure but passes through a phase of atrioventricular block before terminating. Note the retrograde P waves in the surface leads.

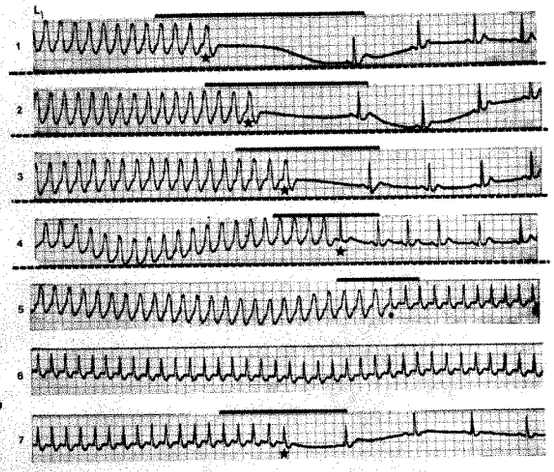

FIGURE 8. Case 6. Recording of lead I (L1) at 25 mm/s. Strips 1 to 5 record five consecutive episodes of paroxysmal supraventricular tachycardia with rate-related left bundle branch block. Several minutes separate each episode. Strips 5, 6 and 7 are continuous. Strips 1 to 5 show the effects of progressively lighter applications of carotid sinus pressure. The **stars** denote the last beat of tachycardia. In strips 1 to 3 the intensity of carotid sinus pressure was so great that the tachycardia terminated before sufficient slowing had occurred and the last beat of tachycardia shows left bundle branch block. In strip 4 a lighter application of carotid sinus pressure slowed the tachycardia sufficiently before its interruption to eliminate the bundle branch block in the last complex. In strip 5, an even lighter application of carotid sinus pressure slowed but did not terminate the tachycardia and eliminated left bundle branch block beginning with the beat with the **dot**. In strip 7 a final application of carotid sinus pressure terminated the tachycardia.

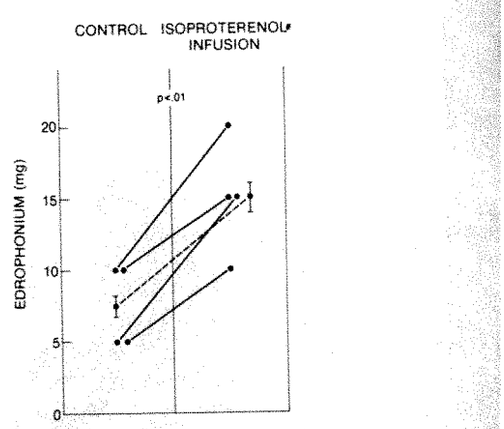

FIGURE 9. Effect of isoproterenol infusion on the minimal dose of edrophonium needed to terminate paroxysmal supraventricular tachycardia in four cases during control condition and during an infusion of isoproterenol 2 μg/min. In each case the dose of edrophonium needed to terminate the tachycardia during infusion of isoproterenol was higher than during the control period.

Effect of background sympathetic tone on vagal termination of paroxysmal supraventricular tachycardia: In four patients whose tachycardia originally terminated with carotid sinus pressure, the mean minimal dose of edrophonium needed to stop subsequent tachycardia increased from 7.5 ± 0.7 mg in control conditions to 15 ± 1.0 mg during isoproterenol infusion (Fig. 9). In parallel with the increased dose of edrophonium required, it became difficult and in some cases impossible for carotid sinus pressure by itself to terminate the tachycardia. In four patients whose tachycardia was terminated only by phenylephrine the minimal dose of phenylephrine and corresponding blood pressure elevation required was reduced by propranolol. The mean minimal phenylephrine dose decreased from a control value of 0.40 ± 0.04 to 0.25 ± 0.03 mg, and the corresponding rise in systolic blood pressure decreased from a control value of 45 ± 0.03 to 30 ± 5 mm Hg (Fig. 10).

Failure of termination of paroxysmal supraventricular tachycardia after vagal blockade: Atropine, 1.2 mg intravenously, was administered to eight patients selected randomly from group B. A subsequent paroxysm of tachycardia could no longer be terminated or transiently slowed in any of the patients by the vagal maneuvers utilized in this study.

Discussion

This study examined a fixed protocol consisting of carotid sinus pressure, Valsalva maneuver and administration of phenylephrine for terminating paroxysmal supraventricular tachycardia in 68 patients. The protocol was chosen because it was well suited to adult patients and allowed semiquantitative grading of potency. All 68 consecutive cases of paroxysmal supraventricular tachycardia could be terminated by at least one of the methods used, a finding in accordance with data from other reports[2,3,5,40–42] citing success rates of 50 to 100 percent using similar vagal maneuvers. Because we did not randomly assign matched patients to each intervention category, we cannot compare the success rate of the individual maneuvers relative to each other.

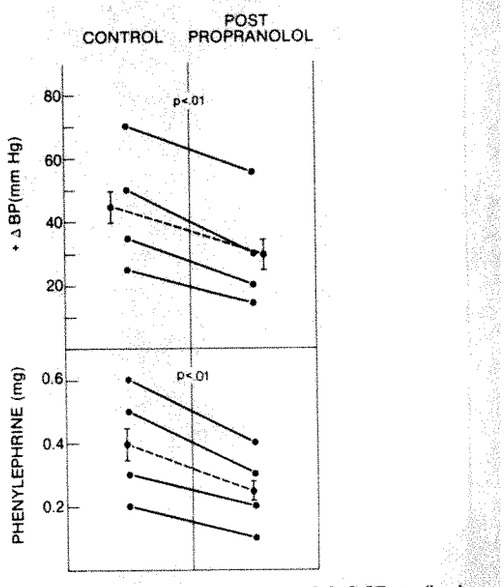

FIGURE 10. Effect of pretreatment with propranolol, 0.07 mg/kg intravenously, on the minimal dose of phenylephrine and increment in blood pressure (ΔBP) needed to terminate supraventricular tachycardia in four cases. The amount of phenylephrine and the increase in blood pressure required to terminate each case was greatly reduced by propranolol.

Relative vagal potency of various maneuvers: Potency testing suggested that administration of phenylephrine was the most potent vagal maneuver. When phenylephrine was used as a standard it was found that patients who originally belonged in this category required a larger dose of this pressor agent and higher blood pressure elevation to terminate their tachycardia than patients whose tachycardia could be terminated by carotid sinus pressure or the Valsalva maneuver. Similarly, it was found that the Valsalva maneuver was more potent than carotid sinus pressure. Other workers have also found that vasopressor therapy is the most potent vagal maneuver in terminating paroxysmal supraventricular tachycardia, with a success rate approaching 100 percent in some reports.[3,5,8,42–44]

These potency results may reflect several factors: (1) The duration of baroreceptor stimulation by the different maneuvers is variable. Carotid sinus pressure provided the shortest period of stimulation (1 to 5 seconds), whereas the pressor action of phenylephrine, which stimulated baroreceptors, was long-lasting. The duration of the Valsalva hypertensive phase was intermediate. (2) The baroreceptors stimulated are different. Carotid sinus pressure provided unilateral carotid baroreceptor stimulation, which reduces sympathetic tone, thus leading to a decrease in blood pressure.[37–39,45,46] This decrease in blood pressure is sensed by the aortic baroreceptors and the contralateral carotid sinus, tending to cause vagal tone withdrawal.[47] Depending on the relative time constants and extent of these effects, variable net increments in vagal tone will be produced by carotid sinus pressure or massage. The Valsalva maneuver and administration of phenylephrine increase blood pressure and thus stimulate all baroreceptor sites. (3) The method of application leads to variable intensity of stimulation. Carotid sinus pressure or massage is dependent on accurate location of the carotid sinus and the duration and force of compression. The Valsalva maneuver is limited by the extent of strain the patient can perform. However, phenylephrine can be given in incremental doses until a pressor response sufficient to terminate the tachycardia has been administered.

Slowing of tachycardia before termination: Slowing of paroxysmal supraventricular tachycardia before its termination has previously been described[2,3,25,33] and was seen in each case in our study. The observation is consistent with studies on vagal nerve stimulation, which prolongs the P-R interval at low intensities of stimulation and causes A-V block at high levels of stimulation.[48,49] The slowing has at least four broad clinical applications: (1) The extent of slowing of tachycardia can be used to study vagal maneuvers in a dose-dependent fashion similar to other antiarrhythmic interventions. (2) Vagal maneuvers producing transient slowing without termination may lead to a mistaken diagnosis of sinus tachycardia (Fig. 6). (3) The absence of any slowing suggests that the A-V node is not part of a tachycardia circuit or that muscarinic blockade is present.[50] (4) Sufficient slowing of tachycardia allows cases with associated rate-related bundle branch block to normalize for one or more cycles before termination. This is of diagnostic importance because some episodes of ventricular tachycardia may terminate after potent vagal maneuvers.[16,17,51] In the case of ventricular tachycardia the abnormal QRS configuration remains until sinus rhythm is restored. Depending on the rate of tachycardia, the extent of slowing and the refractory period of the bundle branches, an episode of paroxysmal supraventricular tachycardia with rate-related aberration can terminate without a phase of normalization (Fig. 8). To maximize the chances of normalization a given vagal maneuver should be applied gently.

Role of sympathetic tone: Enhanced background sympathetic tone may increase the level of vagal tone needed to terminate paroxysmal supraventricular tachycardia. Sympathetic neural tone and sympathetic agonists shorten the refractory properties of A-V nodal cells, speed conduction across this region, and attenuate the effects of the vagus nerve on this region.[49,51–55] An increase in sympathetic tone simulated by an infusion of isoproterenol increased the dose of edrophonium, a relatively pure vagal stimulant, needed to terminate paroxysmal supraventricular tachycardia. Similarly, withdrawal of the effects of sympathetic tone by pretreatment with propranolol greatly facilitated termination of tachycardia by phenylephrine. Thus, there is an active interplay between the background sympathetic tone and the increase in vagal tone required to terminate paroxysmal supraventricular tachycardia. The cases of tachycardia terminated by phenylephrine required the most potent vagal stimulation, possibly because of a high level of background sympathetic tone. The hypotensive effects[56] and the anxiety[57] produced by paroxysms of tachycardia probably elevate sympathetic tone thereby increasing the rate of tachycardia and rendering vagal termination difficult. Apart from drugs that specifically reduce sympathetic tone or enhance vagal tone, reassurance, sedation and the recumbent position may exert similar effects and hence facilitate termination of tachycardia.[18]

Complications of vagal maneuvers: In terminating paroxysmal supraventricular tachycardia in these 68 patients no complications were encountered. Asystole and ventricular fibrillation would be the most serious complications expected and have previously been reported to occur as a side effect of vigorous carotid sinus pressure or massage or edrophonium administration.[58–62] The safety of vagal maneuvers in comparison with other means of tachycardia termination remains to be defined. The longest pause was 3.3 seconds and in most cases (54 of 68) the pauses were 2 seconds or less. These short pauses following termination of paroxysmal supraventricular tachycardia may reflect the relatively young age (average 42 years) of these patients, the lack of sinus nodal and A-V nodal disease, and the graded application of more potent techniques used to increase vagal tone. The brevity of the pauses probably accounts for the absence of any serious side effects in our patient series.

Causes of failure of vagal maneuvers: We have shown that vagal maneuvers are highly effective, reproducible and safe in the termination of paroxysmal supraventricular tachycardia. When vagal techniques fail to terminate paroxysmal supraventricular tachycardia several factors may be operative: (1) There may be improper application of carotid sinus pressure by the physician or an insufficient effort at performing a Valsalva maneuver by the patient. (2) The extent of vagal and sympathetic innervation of the A-V node,[48] its responsiveness to these neural influences[49] and the background level of sympathetic tone may increase the level of vagal tone required.[54,55] (3) There may be an insufficient increase in vagal tone produced by a given amount of baroreceptor stimulation either directly by carotid sinus pressure or by maneuvers or drugs that elevate blood pressure.[63] (4) The extent of vascular reactivity in response to maneuvers that increase blood pressure may be variable.

Therapeutic implications: The type and order of vagal maneuvers that constitute the initial protocol of this study should not be construed to represent a recommended therapeutic approach in the clinical setting. Because various combinations and permutations of these and other maneuvers were not compared with each other, we are not in a position to offer such a recommendation. It may be expected that the type and order of vagal maneuvers chosen will reflect the patient's age, ability to cooperate, hemodynamic status, background cardiac condition and the clinician's preference and experience. For instance, infants and children may be upset by carotid sinus pressure and may be unable to cooperate to perform a Valsalva maneuver, whereas phenylephrine would be free of side effects. By contrast, phenylephrine or other pressor agents should not be used or used only with caution in hypertensive patients. Other vagal maneuvers such as gagging and facial immersion may also be tried prior to the use of intravenous agents.[11,12,64–66] Physiologic procedures such as the Valsalva maneuver should probably precede administration of pharmacologic agents. Drugs that reduce sympathetic tone, such as propranolol, or enhance vagal tone, such as digitalis,[67] may be administered if necessary.

In 36 of the 68 patients, the tachycardia terminated without resort to drug manipulation (with carotid sinus pressure in 33 and with the Valsalva maneuver in 3), and this effect was highly reproducible. Proper selection of patients for instruction in the use of carotid sinus pressure or the Valsalva maneuver might enable them to perform self-termination of episodes of tachycardia without requiring antiarrhythmic drugs or hospitalization. One must concede that the high success rate demonstrated may not easily be replicated by patients under conditions of stress. However, it is likely that oral therapy with antisympathetic drugs like propranolol, or enhancement of vagal tone by digitalis,[67] will increase the ease of termination and success.

Effect of Drugs in the Wolff-Parkinson-White Syndrome

Importance of Initial Length of Effective Refractory Period of the Accessory Pathway

HEIN J. J. WELLENS, MD, FACC
FRITS W. BÄR, MD

The effect of procainamide, quinidine, ajmaline and amiodarone on the effective refractory period of the accessory pathway in the (A-V) anterograde and retrograde directions was studied in relation to the length of this period before drug administration. All patients had the Wolff-Parkinson-White syndrome and were studied with intracavitary recordings and programmed electrical stimulation of the heart using identical basic cycle lengths and test stimulus intervals before and after drug administration. The patients were separated into two groups, those in whom the effective refractory period of the accessory pathway was 270 ms or greater (Group 1) and those in whom it was less than 270 ms (Group 2). In the anterograde direction the magnitude of increase in the length of the effective refractory period of the accessory pathway after drug administration was related to its initial length. Only modest lengthening of this period could be accomplished in patients with an initially short period. In evaluating the effect of drugs in patients with the Wolff-Parkinson-White syndrome, the role of the initial length of the effective refractory period of the accessory pathway should be considered.

Several investigators [1-9] have reported on the effect of various drugs on the duration of the refractory period of the accessory pathway in patients with the Wolff-Parkinson-White syndrome. However, the significance of the initial value of the duration of the refractory period of the accessory pathway on the effect of subsequent drug administration, has not been studied. In this report we describe the effect of procainamide, quinidine, ajmaline and amiodarone on the duration of the refractory period of the accessory pathway in the anterograde and retrograde directions in relation to the initial duration before drug administration.

Methods

Patients: Fifty-nine patients were studied. Their ages ranged from 7 to 54 years; 40 were male and 19 female. In 19 patients the accessory pathway was located between the right atrium and right ventricle and in 40 patients between the left atrium and left ventricle. Patients whose accessory pathway was located in the interventricular septum were excluded because in this condition retrograde conduction over the accessory pathway is difficult to differentiate from that through the atrioventricular (A-V) node. The location of the accessory pathway was determined by the sequence of retrograde atrial activation during A-V reentrant tachycardia and during ventricular pacing [10,11].

Programmed stimulation study: After all medication was stopped for at least 5 days and informed consent had been obtained, a programmed electrical stimulation study was performed. The methods used have been described previously [10]. With use of the single test stimulus technique during atrial and ventricular pacing the effective refractory period of the accessory pathway was determined in anterograde and retrograde directions. At least three basic cycle lengths were used. The first pacing frequency was just above the sinus rate, the second was 100/min and the third 130/min. The shortest refractory period of

From the Department of Cardiology, University of Limburg, Annadal Hospital, Maastricht, The Netherlands. Manuscript received January 15, 1980; revised manuscript received March 31, 1980, accepted April 4, 1980.

the accessory pathway at the three basic cycle lengths was chosen; the maximal difference between values at the three cycle lengths was 20 ms.

The effective refractory period of the accessory pathway in anterograde direction was defined as the longest atrial premature stimulus interval that did not conduct to the ventricle over the accessory pathway from the atrial stimulation site closest to the atrial end of the accessory pathway. The effective refractory period of the accessory pathway in retrograde direction was defined as the longest right ventricular premature stimulus interval that was not followed by eccentric atrial activation (eccentric defined as atrial activation starting not in the His bundle recording or proximal coronary sinus lead, but elsewhere in the right or left atrium).

Drug protocol: Only those patients were accepted who manifested anterograde conduction over the accessory pathway during atrial pacing and retrograde conduction over the accessory pathway during ventricular pacing. After these data were obtained, drugs were given as follows: procainamide, 10 mg/kg body weight intravenously over 5 minutes (16 patients); quinidine gluconate 4 mg/kg intravenously over 5 minutes (10 patients); ajmaline, 50 mg intravenously over 3 minutes (18 patients); and amiodarone, orally, 600 mg daily during week 1 and 300 mg daily during week 2. The latter patients were restudied 2 weeks after the pre-drug investigation. Care was taken to have the intracavitary electrodes at approximately the same positions before and after drug administration. Measurements of the refractory period of the accessory pathway first in a retrograde and then in an anterograde direction were repeatedly made at identical basic cycle lengths and premature stimulus intervals as before drug administration 1 hour after procainamide and quinidine administration, 45 minutes after ajmaline was given and twice with a 15 minute interval after amiodarone. Stimulation was performed at twice threshold. Because drug administration frequently resulted in threshold changes, stimulus strength was repeatedly adjusted during the study.

The maximal changes in duration of the refractory period of the accessory pathway following drug administration were calculated by taking the shortest value of the three basic pacing lengths from pre-drug testing and comparing this value with the maximal value after drug administration at the same basic pacing cycle length. Statistical analysis was performed by using Student's paired t test.

Results

Patient groups: During the evaluation of the effect of drugs on the anterograde and retrograde refractory periods of the accessory pathway it became clear that patients could be separated into two groups:

Group 1: patients with an effective refractory period of the accessory pathway of 270 ms or longer. During evaluation of the anterograde refractory period 25 patients were in this category. The effective refractory period of the accessory pathway ranged from 270 to 520 ms with a mean value (± standard error of the mean) of 329.2 ± 37.9 ms. During evaluation of the retrograde refractory period 20 patients were in this group (range 270 to 400 ms, mean 306.5 ± 27.2 mg).

Group 2: patients with an effective refractory period of the accessory pathway of less than 270 ms. Both in the anterograde and the retrograde direction, exact determination of the refractory period was frequently impossible because the atrium or ventricle became refractory before a block in the accessory pathway developed. In the 34 patients with an anterograde refractory period of the accessory pathway of less than 270 ms, the values ranged from less than 170 to 260 ms; 18 patients had a value of 220 ms or less. There were 39 pa-

tients with a retrograde refractory period of the accessory pathway of less than 270 ms (range less than 200 to 260 ms).

Effect on the effective refractory period of the accessory pathway in the anterograde direction (Table I, Fig. 1): *Group 1: patients with an effective refractory period of the accessory pathway of 270 ms or more:* All four drugs resulted in marked lengthening of the effective refractory period of the accessory pathway. Complete block in the pathway developed in six of seven patients receiving procainamide, in four of five patients after quinidine, in eight of nine patients after ajmaline and in three of four patients receiving amiodarone. Therefore, complete anterograde block in the accessory pathway was produced in 21 (84 percent) of 25 patients. No important difference was observed in the maximal amount of lengthening of the effective refractory period of the accessory pathway produced by the four drugs. Because complete block in the accessory pathway developed in several patients, exact values for the increase in duration of the refractory period cannot be given.

Group 2: patients with an effective refractory period of the accessory pathway of less than 270 ms: On the average only modest prolongation of the effective refractory period of the accessory pathway occurred in this group of patients. In 11 of the 34 patients (4 receiving procainamide, 3 receiving quinidine, 4 receiving ajmaline and none receiving amiodarone) no increase in length of the effective refractory period of the ac-

cessory pathway was observed. Amiodarone was the only drug producing a significant increase in the duration of the effective refractory period of the accessory pathway.

Effect on the effective refractory period of the accessory pathway in retrograde direction (Table II, Fig. 2): *Group 1: patients with an effective refractory period of the accessory pathway of 270 ms or more:* No effect on the effective refractory period of the accessory pathway in the retrograde direction was seen in four patients (two receiving ajmaline and two receiving amiodarone). Complete block in the accessory pathway was seen in three patients (one receiving procainamide and two receiving ajamline). The mean increase in the effective refractory period of the accessory pathway (Table II) was less than that in the anterograde direction (Table I). Only patients receiving ajmaline showed statistically significant lengthening.

Group 2: patients with an effective refractory period of the accessory pathway of less than 270 ms: No effect on the effective refractory period of the accessory pathway was seen in 19 patients (5 receiving procainamide, 4 receiving quinidine, 7 receiving ajmaline and 3 receiving amiodarone). The other patients showed marked individual variations. In three patients (one receiving quinidine and two receiving amiodarone) complete retrograde block in the accessory pathway occurred.

Discussion

Effect of drugs on anterograde conduction of accessory pathway: Our observations indicate that the initial value of the effective refractory period of the accessory pathway played an important role in determining the effect of subsequent drug administration on the duration of this period. In the anterograde direction, when the effective refractory period of the accessory pathway was relatively long (270 ms or greater), all four drugs tested usually resulted in marked prolongation of this period, frequently to the extent of creating complete anterograde block in the accessory pathway. In patients with an initially short duration of the effective refractory period of the accessory pathway the effect was very different. Individually marked differences in the effect of various drugs on the anterograde refractory period of the accessory pathway were seen. Only amiodarone consistently resulted in moderate prolongation of this period. No role was played by a right- or left-sided location of the accessory pathway (Table I). Although, as Pritchett et al.[12] have observed, it is difficult to determine the absolute values of the effective refractory period of the accessory pathway or the exact alterations that occur after drug administration (especially when the initial period is short), the marked difference in the drug response of the two patient groups is too clear to be denied.

A practical implication of our observations is that patients with a short effective refractory period of the accessory pathway, who are at risk of high ventricular rates if atrial fibrillation supervenes and are most in need of lengthening of this period, are least likely to benefit from commercially available drugs. Our findings also raise questions concerning the morphologic or electrophysiologic differences (or both), responsible for the differences in drug responses in the two patient groups. Both procainamide and quinidine gluconate were administered more rapidly than is usual in the United States. We chose this dosage schedule because of our previous experience with its safety[3,13] and because it would give us information about the maximal effect of the drugs, which was clinically relevant to our patients who had frequent tachyarrhythmias. We[3] have previously shown that when these drug protocols are used there is a poor correlation between the electrophysiologic effects of the drug and plasma concentrations. Plasma levels become important only if continuous infusions are used or the drugs are given orally. Therefore plasma levels of the drugs were not determined during the study.

Effect of drugs on retrograde conduction of accessory pathway: In the retrograde direction the accessory pathway behaved differently. On the whole, lengthening of the effective refractory period of the accessory pathway was less marked. Complete retro-

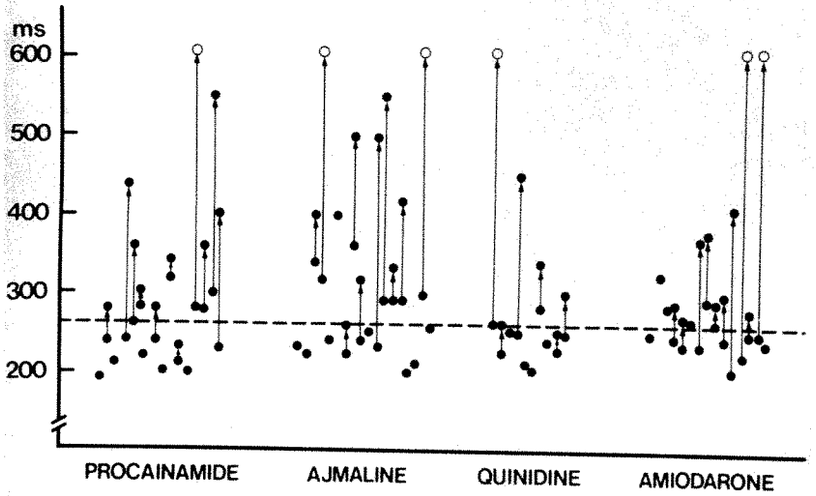

FIGURE 2. Effect of the four study drugs on the effective refractory period of the accessory pathway in the retrograde direction. Symbols as in Figure 1.

grade block after drug administration was observed in only six patients (three with an effective refractory period of the accessory pathway of less than 270 ms and three with a longer effective refractory period).

In contrast to findings in the anterograde direction, in the retrograde direction there were no important differences between drug responses in the two patient groups. However, the effect of drugs on retrograde conduction may have been influenced by the site of stimulation, which was in the apex of the right ventricle, far from the ventricular end of the accessory pathway.

As in previous studies, [3,7] our observations showed that the effect of drugs on the effective refractory period of the accessory pathway in the anterograde and retrograde directions can differ markedly. Although complete anterograde block over the accessory pathway was obtained in 21 (36 percent) of 59 patients after drug administration, complete retrograde block was observed in only 6 instances (10 percent). These findings explain why in some patients an increasing incidence of circus movement tachycardia can be seen after the administration of a drug that completely blocks anterograde conduction through the accessory pathway but has little or no effect on retrograde conduction over the accessory pathway. It is clear that observations on the effect of a drug on an intracardiac pathway in one direction can never predict the effect of that drug on the electrophysiologic properties of that pathway in the other direction.

Our data on differences in the effect of drugs on the accessory pathway in relation to the initial electrophysiologic properties of that pathway may also apply to other structures participating in the genesis of reentrant arrhythmias in the human heart. This might be an important factor responsible for differences in the effectiveness of antiarrhythmic drugs among patients.

Amiodarone and atrial fibrillation in Wolff-Parkinson-White syndrome: Among the many factors that determine the ventricular rate during atrial fibrillation in patients with the Wolff-Parkinson-White syndrome the duration of the anterograde refractory period of the accessory pathway is an important one.[14] Our data indicate that when the duration is short and there is a documented episode of atrial fibrillation with rapid ventricular rate, the protection offered by drugs known to prolong refractoriness in the accessory pathway must be individually assessed. Because factors other than the refractoriness of this pathway play a role in determining ventricular rate during atrial fibrillation, it is preferable that drugs be evaluated by the induction of atrial fibrillation before and after drug administration. However, in our study, this procedure would have required repeated cardioversions in several of our patients. In patients with a short anterograde refractory period of the accessory pathway a statistically significant lengthening of this period was observed only after administration of amiodarone. Although this increase was relatively modest, a lengthening of 75 ms in a patient with an anterograde effective refractory period of the accessory pathway of 200 ms will result in a decrease in theoretical maximal ventricular rate during atrial fibrillation from 300 to 220 beats/min. This effect of amiodarone might protect the patient with the Wolff-Parkinson-White syndrome and a short refractory period of the accessory pathway against life-threatening ventricular rates if atrial fibrillation supervenes.

Pharmacokinetic-Hemodynamic Studies of Nitroglycerin Ointment in Congestive Heart Failure

PAUL W. ARMSTRONG, MD, FACC*
JOYCE A. ARMSTRONG, MSc
GERALD S. MARKS, DPhil

with the technical assistance of
JAMES McKINVEN
SUSAN SLAUGHTER

Kingston, Ontario, Canada

The aim of this study was to determine the bioavailability of nitroglycerin after application of nitroglycerin ointment in patients with heart failure and to examine whether a correlation exists between plasma nitroglycerin and its hemodynamic effects. The dose of nitroglycerin ointment selected was based on the prior hemodynamic response of individual patients to an intravenous infusion of nitroglycerin. Nine patients received 1 to 2 inches of nitroglycerin ointment on a single skin site (small dose group) and five patients received 4 inches (2 inches to two separate skin sites, large dose group).

There was good correlation between the dose of nitroglycerin ointment and bioavailability (area under the plasma concentration time curve from 0 to 240 minutes) ($r = 0.81$, $p < 0.001$). We observed a decrease in both pulmonary capillary wedge pressure and right atrial pressure 30 minutes after application of nitroglycerin ointment. The maximal changes in pulmonary capillary wedge pressure were from 28 ± 7 to 23 ± 8 mm Hg and in right atrial pressure from 14 ± 7 to 11 ± 6 mm Hg. There was a greater decrease in pulmonary capillary wedge pressure in the small dose group (31 percent) compared with the large dose group (13 percent) ($p < 0.001$). Plasma nitroglycerin concentration in the small dose group increased to 3.1 ± 3.0 ng/ml at 60 minutes and remained at that level through 240 minutes. In the large dose group a plasma nitroglycerin level of 8.9 ± 4.0 ng/ml was achieved at 60 minutes and sustained through 240 minutes. Despite this plasma nitroglycerin level there was little decline in pulmonary capillary wedge pressure. This study demonstrates a good relation between the dose of nitroglycerin ointment and nitroglycerin bioavailability; nitroglycerin ointment also provides therapeutic levels of nitroglycerin associated with substantial hemodynamic benefit in selected patients with cardiac failure.

Nitroglycerin applied to the skin in ointment form enters the circulation in a manner that bypasses the gastrointestinal tract and portal circulation. Since 1944, nitroglycerin has been adminstered percutaneously in ointment form for the therapy of peripheral circulatory disorders.[1] In 1955, Davis et al.[2] reported that this agent had favorable effects in patients with angina pectoris. This finding was later confirmed by Reichek et al.[3] who demonstrated at least a 3 hour increase in exercise capacity in patients with angina pectoris. Studies[4–6] from our own institution and elsewhere in patients with angina pectoris, myocardial infarction and congestive heart failure have demonstrated that the hemodynamic effects of nitroglycerin ointment are maximal between 60 to 90 minutes after its application and persist for at least 4 to 6 hours.

Expansion of the indications for the use of nitrate therapy has generated a need for and the development of preparations with a longer duration of action than the conventional sublingual form.[7] One such preparation is oral isosorbide dinitrate, which has been demonstrated to produce hemodynamic effects for approximately 6 hours after adminstration.[8] Although this agent is effective, in some clinical situations

the oral route of drug administration may be unsatisfactory, for example, when the oral route is precluded by nasogastric suction or paralytic ileus or the absorption of oral agents is compromised by a malabsorption syndrome. In such patients, the percutaneous route may constitute an effective alternative. Another circumstance in which the absorption of oral medications may be both variable and incomplete is congestive heart failure.[9] Whether the percutaneous route is preferable in this setting is as yet unknown.

In previous studies of patients with heart failure a subset who did not respond to nitroglycerin ointment was identified with hemodynamic monitoring.[10,11] Because plasma levels of nitroglycerin were unavailable, the possibility existed that this lack of response resulted from an inability to achieve adequate plasma concentrations of nitroglycerin. Accordingly, we undertook a pharmokinetic-hemodynamic study of nitroglycerin ointment administered percutaneously to patients with congestive heart failure.

Our objectives were (1) to determine the bioavailability of nitroglycerin after application of nitroglycerin ointment in patients with heart failure; and (2) to examine whether a correlation exists between the concentration of nitroglycerin in plasma and its hemodynamic effects, both after application of nitroglycerin ointment and after its removal.

Methods

Patients: Fourteen patients with congestive heart failure formed the study group: There were 11 men and 3 women with a mean age of 53 years (range 38 to 67). Three had cardiomyopathy, seven had chronic arteriosclerotic heart disease and four were studied within 1 month of a myocardial infarction; these patients were all in New York Heart Association functional class III or IV[12] and refractory to conventional therapy including administration of digoxin and furosemide. Four patients with diabetes were insulin-dependent. Five had received isosorbide dinitrate for at least 3 weeks before this study. All drugs except digoxin and insulin were withheld for at least 24 hours before onset of the study.

Hemodynamic studies: After informed consent was obtained, the patients were fitted with instruments for hemodynamic monitoring in a standard fashion. This included the placement of a triple lumen thermodilution Swan-Ganz catheter in the pulmonary artery and a Teflon® cannula in the radial artery. Right atrial, pulmonary arterial and pulmonary capillary wedge pressures (obtained by balloon occlusion) and systemic arterial pressure were monitored. The cardiac output was measured, at least in duplicate, with the thermodilution technique (injection of 10 ml of ice-cold 5 percent dextrose in water into the right atrium).[13]

Intravenous nitroglycerin: Nitroglycerin was prepared for intravenous use as a 0.5 percent solution in ethanol. A 9.5 percent lactose mixture (Parke-Davis Company, Brockville, Ontario, Canada) (6.3 g) was added to ethyl alcohol (99 percent) to a total volume of 120 ml. The alcoholic supernatant was decanted and passed through a 0.22 Millex® millipore filter. The solution was assayed using a spectrophotometric technique before being reassayed using our gas-liquid chromatographic method.[14] Immediately before use, the nitroglycerin solution was added to 5 percent dextrose in water and contained in glass bottles to produce a concentration of 100 μg/ml.

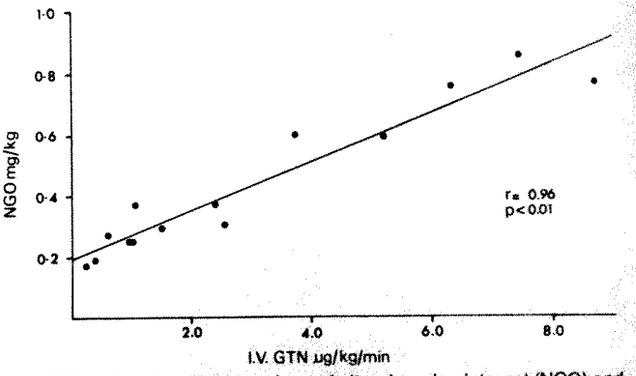

FIGURE 1. Relation between dose of nitroglycerin ointment (NGO) and peak intravenous nitroglycerin (I.V. GTN) infusion rate. p = probability; r = correlation coefficient.

After a control period of 30 minutes, during which the hemodynamic measurements were demonstrated to be reproducible, intravenous nitroglycerin was infused at an initial rate of 15 to 20 μg/min. The aim was to reduce pulmonary capillary wedge pressure by at least 25 percent, and the infusion was increased in stepwise fashion (50 percent increments of prior rate) every 10 to 15 minutes until either the desired hemodynamic end point was achieved or a greater than 10-fold increment in the initial infusion rate had been reached. The final infusion rate was maintained until a hemodynamic steady state was achieved, which required approximately 15 to 20 minutes. The infusion was then discontinued and monitoring performed for at least an additional 30 to 60 minutes until return to control hemodynamic values had been demonstrated.

Nitroglycerin ointment groups: We[15,16] have previously found that the hemodynamic response to intravenous nitroglycerin is useful in establishing the response to and selecting the dose of other forms of nitrate therapy.[15,16] In this study, patients in whom the hemodynamic end point was reached at an intravenous nitroglycerin infusion rate of 2.5 μg/kg per min or less received 2 inches (5 cm) or less of nitroglycerin ointment. The nine patients in this group had mean (± standard deviation) intravenous nitroglycerin infusion rate of 1.2 ± 0.8 μg/kg per min. Patients who received more than 2.5 μg/kg per min of intravenous nitroglycerin received 4 inches (10 cm) of nitroglycerin ointment. Among the five patients in this group, the hemodynamic end point was reached in only one, and the average intravenous nitroglycerin infusion rate was 6.3 ± 1.9 μg/kg per min. The relation between the dose of intravenous nitroglycerin and nitroglycerin ointment is shown in Figure 1. Detailed examination of the pharmacokinetic-hemodynamic response to intravenous nitroglycerin in nine of our patients has been reported separately.[16]

Nitroglycerin ointment (Nitrol® 2 percent, Kremers-Urban Company, Milwaukee, Wisconsin) was applied to the chest or flank over a 3 by 3 inch (7.6 by 7.6 cm) square area. As indicated, the dose selected was based on the patient's response to prior intravenous administration of nitroglycerin (Fig. 1). When more than 2 inches was applied, a second 3 by 3 inch site was utilized. After application of nitroglycerin ointment, hemodynamic monitoring was performed at frequent intervals through 240 minutes: In selected instances the period of monitoring was prolonged to 480 minutes. The occlusive dressing was then removed, the residual ointment scraped from the skin and the skin site washed with alcohol.

Arterial blood samples were withdrawn during the control period before the administration of intravenous nitroglycerin

TABLE I

Summary of Hemodynamic Response to Nitroglycerin Ointment (n = 14)

Time Period (mm)	HR	PCW	RAP	MAP	CI	SI	TPR
C	93 ± 16	28 ± 7	14 ± 7	93 ± 20	2.2 ± 0.7	23.9 ± 8.3	22.3 ± 10.4
30	93 ± 15	24 ± 8	12 ± 6	90 ± 17	2.3 ± 0.6	25.5 ± 6.5	20.4 ± 8.6
60	93 ± 15	24 ± 8	11 ± 6	90 ± 20	2.3 ± 0.6	24.9 ± 6.8	20.7 ± 8.2
90	92 ± 15	24 ± 8	12 ± 7	89 ± 21	2.3 ± 0.5	25.1 ± 4.0	20.6 ± 9.5
120	92 ± 15	23 ± 8	11 ± 6	90 ± 20	2.3 ± 0.5	25.0 ± 6.8	21.0 ± 8.6
240	91 ± 15	24 ± 9	12 ± 8	86 ± 18	2.4 ± 0.7	27.6 ± 9.3	19.9 ± 9.7
p	NS	<0.0005	<0.0005	NS	<0.05	<0.02	NS

All summary values represent mean ± standard deviation; p values represent a linear regression analysis performed on average percent from control value (t = 0) against time.

C = control value; CI = cardiac index (liters/min per m^2; HR = heart rate (beats/min); MAP = mean arterial pressure (mm Hg); NS = not significant; PCW = pulmonary capillary wedge pressure (mm Hg); RAP = right atrial pressure (mm Hg); SI = stroke index (ml/beat per m^2); TPR = total peripheral resistance (units).

as well as just before the application of nitroglycerin ointment and at 60, 90 and 240 minutes after the application of ointment. In some instances, additional samples were available up to and including 480 minutes as well as 30 minutes after the removal of nitroglycerin ointment. Blood samples were immediately centrifuged at 5° C and the decanted plasma was frozen at −20° C. Subsequent analysis was performed using a gas-liquid chromatograph with isosorbide dinitrate or dinitrobenzene as the internal standard (14).

Analysis of data: Derived calculations were performed using the formulas SI = CI/HR and TPR = MAP-RAP/CO, where SI = stroke index in ml/beat per m^2, CI = cardiac index in liters/min per m^2, TPR = total peripheral resistance in units, MAP = mean arterial pressure in mm Hg, CO = cardiac output in liters/min and RAP = right atrial pressure in mm Hg.

Statistical comparisons of measurements were made using regression analysis and Student's t test with paired and unpaired observations used when appropriate. The correlations and their significance were tested using Fisher's F test. The area under the plasma concentration time curve (from 0 to 240 minutes and from 0 to 480 minutes) was determined with trapezoidal integration using discrete points.

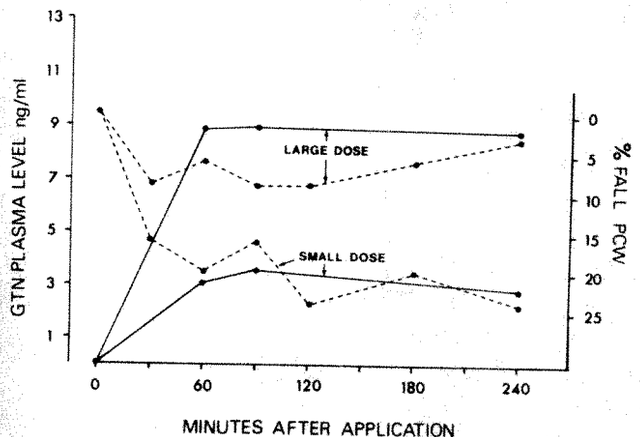

FIGURE 2. Plot of the relation between plasma nitroglycerin (glyceryl trinitrate) (GTN) concentration (**solid lines**) and percent decrease in pulmonary capillary wedge pressure (PCW) (**dashed lines**) for the groups receiving small dose (2 inches or less) and large dose (4 inches) of nitroglycerin ointment. Standard deviations for plasma nitroglycerin and percent reduction in pulmonary capillary wedge pressure are equal to or less than ±4.3 ng/ml and ±11.5 percent, respectively, in the large dose group and equal to or less than ±3.1 ng/ml and ±9.5 percent in the small dose group.

Results

The relation between the dose of nitroglycerin ointment selected and the peak nitroglycerin infusion rate (that is the dose that either produced a 25 percent reduction in pulmonary capillary wedge pressure or was greater than 10 times the initial infusion rate) is illustrated in Figure 1. A regression analysis performed between the doses of the two modes of nitroglycerin adminstration demonstrates a good correlation (r = 0.96, probability [p] <0.01).

Hemodynamic response to nitroglycerin: Table I presents a summary of the hemodynamic response to nitroglycerin ointment at time periods up to and including 240 minutes after application. To determine the effect of treatment, a linear regression analysis was performed on the percent change from the control level (t = 0 value) against time. No significant changes were observed in heart rate, mean arterial pressure or total peripheral resistance. In all cases the slope of the line was not significantly different from 0 (typically t value < 1.8), suggesting that there is no consistent change in level with time. For pulmonary capillary wedge pressure, the average percent reduction, as measured by the intercept of the fitted line, was 15 percent with a t value of 5.8 (p <0.0005); for right atrial pressure, the percent reduction was 19 percent (t = 4.8, p <0.0005); for cardiac index, the percent increase was 8 percent (t = 2.1, p <0.05); for stroke index, the percent increase was 8 percent (t = 2.4, p <0.02).

Relation between bioavailability of nitroglycerin ointment and peak hemodynamic effect (Table II): Changes in pulmonary capillary wedge pressure and right atrial pressure proved to be the most sensitive indicators of the hemodynamic response to nitroglycerin in our previous studies, and therefore the peak changes in these measurements are shown in Table II.[15,16] We

TABLE II

Relation Between Bioavailability of Nitroglycerin Ointment and Peak Hemodynamic Effect

	Dose of NGO		Nitroglycerin Bioavailability	Peak Hemodynamic Effect			
				Control PCW	Decrease in PCW	Control RAP	Decrease in PCW
Case	(inches)	(mg/kg)	AUC_{0-240} (ng·min/ml)	(mm Hg)	(%)	(mm Hg)	(%)

Statistical significance: Paired *t* test (percent decrease in pulmonary capillary wedge and right atrial pressures): * $p < 0.001$; † $p < 0.025$. Unpaired *t* test (small dose versus large dose group) for area under the concentration-time curve, control value and percent decrease in pulmonary capillary wedge pressure and control value and percent decrease in right atrial pressure: $p < 0.005$, < 0.005, < 0.005, NS and NS, respectively.

AUC = area under concentration-time curve; NGO = nitroglycerin ointment; NS = not significant; PCW = pulmonary capillary wedge pressure; RAP = right atrial pressure; SD = standard deviation.

have arbitrarily divided the data into two subsets based on the dose of nitroglycerin ointment applied. The small dose group (n =9) received 1 to 2 inches or 12.5 to 25 mg of nitroglycerin ointment on a single skin site. The large dose group (n = 5) received 4 inches or 50 mg of nitroglycerin ointment (2 inches applied to two separate skin sites). The control value of pulmonary capillary wedge pressure was higher in the large than in the small dose group, (33 versus 26 mm Hg, $p < 0.005$). After application of nitroglycerin ointment there was a greater decrease in pulmonary capillary wedge pressure in the small (31 percent) than in the large dose group (13 percent, $p < 0.005$). There was no significant difference in the control value or in the changes in right atrial pressure between the two groups. The area under the plasma concentration-time curve from 0 to 240 minutes was significantly less in the small than in the large dose group ($p < 0.005$).

Changes in pulmonary capillary pressure correlated with plasma nitroglycerin concentration: In Figure 2, the percent changes from the control value of pulmonary capillary wedge pressure are displayed over the 240 minute period after application of nitroglycerin ointment to allow for comparison with plasma nitroglycerin concentration data in the large and small dose groups. In the small dose group, pulmonary capillary wedge pressure decreased substantially at 30 minutes, reaching its maximal reduction of 23 percent at 120 minutes and remaining depressed through 240 minutes. Plasma nitroglycerin concentration in this group increased to 3.1 ± 3.0 (standard deviation) ng/ml at 60 minutes and remained at that level throughout the remainder of the sampling period. In the large dose group a plasma nitroglycerin level of 8.9 ± 4.0 ng/ml was achieved at 60 minutes and was sustained throughout the 240 minute sampling period. Despite this plasma nitroglycerin concentration there was little decline in pulmonary capillary wedge pressure.

We analyzed the decrease in pulmonary capillary wedge pressure produced by nitroglycerin ointment as a function of resting pulmonary capillary wedge pressure, cardiac index and total peripheral resistance and found that none of these indexes were of value in predicting the change in pulmonary capillary wedge pressure after application of nitroglycerin ointment ($r \leq 0.53$, in all instances).

In four patients (Cases 4, 10, 11 and 14), hemodynamic and plasma nitroglycerin data were available for 480 minutes after application of nitroglycerin ointment (Fig. 3). There was a modest early reduction in right atrial pressure that was sustained through 360 minutes and returned toward the control value at 480 minutes. There was a small and sustained reduction in pulmonary capillary wedge pressure. The plasma nitroglycerin

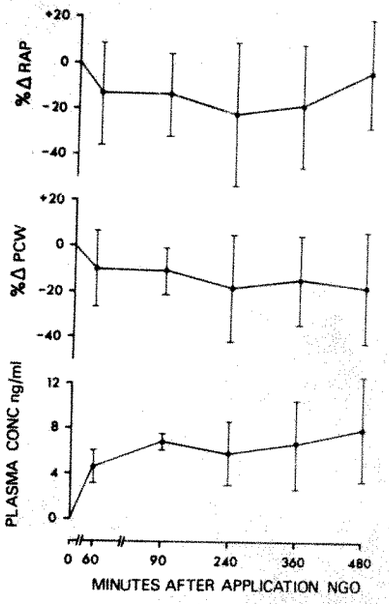

FIGURE 3. Hemodynamic and plasma nitroglycerin data in four patients studied for 480 minutes after application of nitroglycerin ointment (NGO). All data represent mean values ± standard deviations. CONC = concentration; PCW = pulmonary capillary wedge pressure; RAP = right atrial pressure.

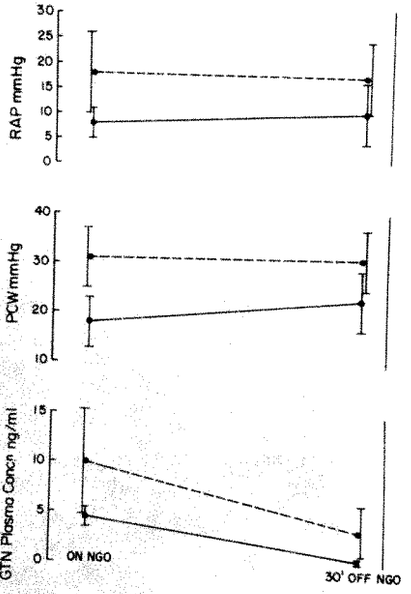

FIGURE 4. Influence of removal of nitroglycerin ointment (NGO) in 11 patients. "On NGO" indicates the last observation before removal. Seven patients are in the small dose group (**solid lines**) and four in the large dose group (**dashed lines**). Significant changes occurred in pulmonary capillary wedge pressure (PCW) in the small dose group (18 to 23 mm Hg, $p < 0.025$) and in nitroglycerin (GTN) plasma concentration ($p < 0.05$ for both groups). The plasma concentration data in the small dose group are based on values in three patients.

levels were elevated to nearly 5 ng/ml at 60 minutes and remained elevated through the balance of the sampling period.

In four patients in the large dose group and in seven in the small dose group, we analyzed the effects of removing nitroglycerin ointment. Six patients were studied to 240 minutes, two to 360 minutes and three to 480 minutes (Fig. 4). There was little change in either right atrial or pulmonary capillary wedge pressure in the large dose group 30 minutes after removal of nitroglycerin despite a substantial decrease in plasma nitroglycerin. By contrast, in the small dose group there was a slight rise in right atrial pressure and a significant increment in pulmonary capillary wedge pressure 30 minutes after removal of nitroglycerin. Plasma nitroglycerin, available in three patients in the small dose group, showed a sharp decrease similar to that noted in the large dose group.

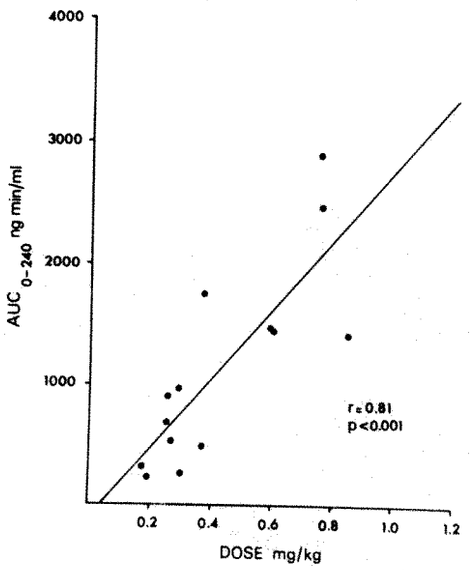

FIGURE 5. Linear regression analysis of relation between the area under the plasma concentration-time curve from 0 to 240 minutes (AUC_{0-240}) and dose of nitroglycerin ointment for the total study group ($r = 0.81$; $p < 0.001$).

The relation between plasma nitroglycerin concentration and the dose of nitroglycerin ointment applied was testing using a linear regression analysis. In all patients the relation between peak plasma nitroglycerin and dose of nitroglycerin ointment in mg/kg was $r = 0.89$ ($p < 0.001$); the relation between the area under the concentration-time curve (AUC_{0-240}) and dose of nitroglycerin ointment was $r = 0.81$ ($p < 0.001$) (Fig. 5). The best relation was observed in the four patients shown in Figure 3 in whom the correlation between the area AUC_{0-480} and the dose of nitroglycerin ointment was 0.98 ($p < 0.02$).

Discussion

Bioavailability of nitroglycerin ointment: This study documents the bioavailability of nitroglycerin when delivered percutaneously to patients with congestive heart failure. There was in general a good relation between the area under the plasma concentration-time curve from 0 to 240 minutes and the dose of nitroglycerin ointment (Fig. 5). This relation improved

when it was examined in the four patients who were observed for 480 minutes after application of nitroglycerin ointment (Fig. 3). The previously demonstrated short half-life of nitroglycerin of 1.9 minutes coupled with the observation of sustained plasma nitroglycerin levels 480 minutes after application of nitroglycerin ointment indicates that absorption of nitroglycerin must have continued throughout the entire period of application.[16] This suggests that "flip-flop" kinetics are operative when nitroglycerin ointment is applied; that is, the plasma concentration over the study period is directly dependent on continuing absorption.[17]

Despite the good relation between dose of nitroglycerin ointment and area under the plasma concentration-time curve from 0 to 240 minutes, some interpatient variability occurred. There are a variety of reasons why interpatient differences in bioavailability might be expected after application of similar doses of nitroglycerin ointment. These differences relate in part to variations in percutaneous absorption as modulated by skin perfusion, permeability and thickness. Moreover, differences in both systemic perfusion and venous congestion in these patients with heart failure would be expected to alter volume of distribution, rate of hepatic metabolism and, therefore, clearance of nitroglycerin.[18] The interpatient variability would probably have been diminished had all patients been evaluated throughout the complete time course of absorption, which is as yet unknown.

Examining our data in the light of the experimental studies of Horhota and Fung[19] is of considerable interest. These investigators studied the effects of topical application of nitroglycerin ointment to the abdominal skin surface of rats; they demonstrated a wide variation in the nitroglycerin plasma concentration-time curve among individual rats despite similar doses. They also found that the concentration of blood nitroglycerin remained elevated throughout the duration of the 4 hour study period. Analysis of surface sections after the 4 hour absorption experiments revealed that nearly 60 percent of the applied drug could be recovered, indicating that significant quantities of the drug were still available for absorption. Although in the current study we found that plasma nitroglycerin decreased substantially after removal of nitroglycerin ointment, it was still detectable 30 minutes thereafter. This finding was unexpected in view of the short half-life of nitroglycerin of 1.9 minutes and it suggests that a depot for nitroglycerin exists in the skin of human subjects, as it does in rats, after percutaneous application.[16]

Beneficial hemodynamic effects of nitroglycerin ointment: This study confirms that nitroglycerin ointment provides prompt and sustained hemodynamic benefit in selected patients with congestive heart failure. The patients in the small dose group who were characterized as sensitive to nitroglycerin by prior intravenous nitroglycerin infusion demonstrated hemodynamic benefit concomitant with the appearance of approximately 3 ng/ml of nitroglycerin in plasma. The hemodynamic effects were already clearly evident 30 minutes after application of nitroglycerin ointment at a time when the plasma level was probably less than 3 ng/ml (Fig. 2). This concentration of nitroglycerin is within the therapeutic range of 1.2 to 11.1 ng/ml defined in our previous study of 16 patients with congestive heart failure who received intravenous nitroglycerin.[16]

Although there appeared to be a good correlation between plasma nitroglycerin and its hemodynamic effects in the small dose group, a subset of patients has again been identified who demonstrate minimal response to nitroglycerin despite achieving plasma concentrations of 9 ng/ml. These findings were anticipated from the patients' prior attenuated response to intravenous nitroglycerin. The attenuated response in these patients is also demonstrated by the lack of hemodynamic alteration after removal of nitroglycerin ointment despite a substantial decrease in plasma nitroglycerin.

We[16] have previously shown that some patients with heart failure may respond to nitroglycerin with a reduction in right atrial pressure, but little change in left ventricular filling pressure.[16] This appeared to be the case in Patients 10, 12 and 13 and may be partly related to asymmetric distribution of cardiac disease expressed by differing compliance characteristics of the two ventricles.[20]

Factors influencing response to nitroglycerin: A variety of factors may have influenced the response to nitroglycerin in this study. Nitrate responsiveness could not be predicted from the value of the resting cardiac index, total peripheral resistance or pulmonary capillary wedge pressures.[21] Three of the five patients in the large dose group had diabetes, and two of these three were insulin-dependent; small vessel disease secondary to the diabetes could have modified the hemodynamic response in these patients. Prior nitrate therapy did not appear to be a predictor of response to nitroglycerin ointment because only two of the five patients who received prior nitrate therapy were in the large dose group.[22] The amount of circulating catecholamines and angiotensin is known to be increased in some patients with heart failure; variations in the levels of these substances would also be expected to alter the response of the peripheral circulation to pharmacologic therapy.[23,24] Because the concentration of nitroglycerin in plasma was in the therapeutic range in the patients who did not respond, absorption of the drug from ointment was confirmed. Lack of response was not due to failure of drug delivery but probably represented target organ resistance in peripheral arterioles and veins. This resistance cannot be predicted from control hemodynamic indexes, but it can be anticipated by prior intravenous nitroglycerin infusion and is best detected by hemodynamic monitoring.

Clinical implications: From these data we conclude that nitroglycerin ointment provides therapeutic levels of nitroglycerin that are associated with substantial hemodynamic benefit in selected patients with heart failure. Therapeutic plasma concentrations of nitroglycerin are demonstrable through at least 480 minutes and probably persist for a longer period. In those cases in which an attenuated response is found during intra-

venous infusion of nitroglycerin, large doses of nitroglycerin ointment (4 inches) are also unlikely to be of benefit. Further investigation is required to (1) document the complete time course of nitroglycerin bioavailability and hemodynamics after application of nitroglycerin ointment, (2) explore the mechanism of resistance of nitroglycerin, and (3) determine whether tolerance occurs in responsive patients.

Acknowledgment

We acknowledge the capable assistance of Sheila Dee, RN, Marlene Adam, BNSc, the nurses of the Coronary Care Unit of the Kingston General Hospital, and the assistance of Assil Bassili, BPharm in the preparation and spectrophotometric analysis of the intravenous nitroglycerin, the statistical advice of Donald G. Watts, PhD, and the secretarial assistance of Anne Baron and Jeanine MacRow.

Simultaneous Anterograde Fast-Slow Atrioventricular Nodal Pathway Conduction After Procainamide

JOSEPH ANTHONY C. GOMES, MD, FACC
PRITPAL S. KANG, MD
GEORGE KELEN, MD
RAHMAN KHAN, MD, FACC
NABIL EL-SHERIF, MD, FACC

Brooklyn, New York

Three patients with paroxysmal supraventricular tachycardia underwent electrophysiologic studies that included His bundle recordings, incremental atrial and ventricular pacing and extrastimulation before and after intravenous infusion of 500 mg of procainamide. In all three patients the tachycardia was induced during atrial pacing or premature atrial stimulation, or both. Two of the three patients had discontinuous atrioventricular (A-V) nodal curves with induction of a slow-fast tachycardia during failure in anterograde fast pathway conduction and one patient had a smooth A-V nodal curve with induction of a slow-fast tachycardia at critical A-H interval delays. After procainamide: (1) in all three patients atrial pacing induced A-V nodal Wenckebach periodicity (cycle length 300 to 400 ms) resulting in simultaneous anterograde fast and slow pathway conduction (one atrial beat resulting in two QRS complexes) and retrograde fast pathway conduction initiating an echo response or a slow-fast tachycardia, or both; (2) in all three patients there was enhanced conduction and shortening of refractoriness of the anterograde fast pathway and depressed conduction and lengthening of refractoriness of the retrograde fast pathway; and (3) in two patients there was inability to sustain tachycardia because of selective block within the retrograde fast pathway. In conclusion: (1) procainamide altered conduction and refractoriness of the anterograde fast and slow pathways so that simultaneous conduction could occur during atrial pacing, resulting in a double ventricular response and a slow-fast echo or tachycardia, or both; and (2) the differential effects of procainamide on anterograde fast and retrograde fast pathways suggests two functional A-V nodal fast pathways, one for anterograde and the other for retrograde conduction.

Electrophysiologic studies have established reentry within the atrioventricular (A-V) nodal region as the most common mechanism of paroxysmal supraventricular tachycardia.[1–8] These studies have also revealed that, although in some patients the induction of A-V nodal reentrant tachycardia is associated with failure in anterograde fast pathway conduction resulting in anterograde conduction solely in the slow pathway and retrograde conduction over the recovered anterograde fast pathway,[4–6] in others the induction of A-V nodal reentry is associated with attainment of a critical A-V nodal conduction delay and retrograde conduction over a fast retrograde pathway.[2,9] Nonetheless, reciprocation within a slow and fast pathway in the region of the A-V node is believed to be the electrophysiologic basis of A-V nodal reentry. In contrast, simultaneous anterograde fast and anterograde slow pathway conduction resulting in a slow-fast tachycardia is exceedingly rare.[10] In this paper we describe (1) the electrophysiologic findings in three patients with A-V nodal reentry who demonstrated simultaneous anterograde fast and slow pathway conduction resulting in a double ventricular response and a slow-fast echo or tachycardia, or both, after the administration of procainamide; and (2) differential effects of procainamide on the anterograde and retrograde fast pathways. The implications of these observations are discussed.

Methods

Study patients: Three patients with a history of palpitations and electrocardiographically documented paroxysmal supraventricular tachycardia were studied after the nature of the procedure was explained and signed consent obtained. One patient had atherosclerotic heart disease and the remaining two patients had no evidence of cardiac disease. None had a recent myocardial infarction, electrolyte or metabolic abnormalities or the Wolff-Parkinson-White syndrome and none had received any cardioactive medications for at least 4 days before the study.

Electrophysiologic study: Three quadripolar catheters were introduced percutaneously under local anesthesia and positioned in the region of the high right atrium, at the level of the tricuspid valve for recording His bundle activity[11] and in the right ventricular apex. The proximal poles of the atrial and ventricular catheters were utilized for recording and the distal poles for stimulation. Two or more standard electrocardiographic leads, intracardiac electrograms at frequency settings of 40 to 500 hertz and time lines generated at 40,200 and 1,000 ms were displayed on a multichannel oscilloscope (VR-12, Electronics for Medicine, White Plains, New York) and reproduced on thermal paper at a paper speed of 100 to 150 mm/s.

Atrial and ventricular pacing were performed up to the onset of anterograde and retrograde block or up to a heart rate of 220 beats/min. During pacing-induced A-V nodal Wenckebach cycles, the stimulator was periodically turned off for observation of subsequent spontaneous events. The atrial and ventricular extrastimulus techniques were employed to determine the refractory periods of the atrioventricular (A-V) and ventriculoatrial (V-A) conduction system at two or more cycle lengths. After completion of control studies, procainamide in a total dose of 500 mg was administered intravenously at a rate of 50 mg/min and studies were repeated within 10 minutes of drug administration. Blood samples for serum procainamide levels were drawn in all three patients.

Definition of terms: ***Anterograde conduction intervals and refractory periods:*** These were defined as previously described.[12]

Retrograde conducting intervals and refractory periods: *V-A conduction time* was measured from the stimulus artifact during ventricular pacing to the onset of the retrograde low septal atrial electrogram on the His bundle tracing.

S_2-H_2 interval was measured from the onset of the premature stimulus artifact (S_2) to the onset of the retrograde His bundle electrogram (H_2)

H_2-A_2 interval was measured from the onset of the retrograde His bundle deflection (H_2) to the onset of the retrograde low septal electrogram (A_2) on the His bundle tracing.

Retrograde functional refractory period of the V-A conduction system was defined as the shortest A_1-A_2 interval in response to any range of S_1-S_2 or V_1-V_2 intervals.

Retrograde effective refractory period of the V-A conduction system was defined as the longest S_1-S_2 or (V_1-V_2) interval at which S_2 or V_2 failed to evoke an A_2 response. This interval is determined by the His-Purkinje system when S_2 is not followed by H_2, provided that H_2 is identified before block or by the A-V nodal region, in which case the retrograde His bundle deflection (H_2) is not followed by A_2.

Retrograde functional and effective refractory periods of the His-Purkinje system and the effective refractory period

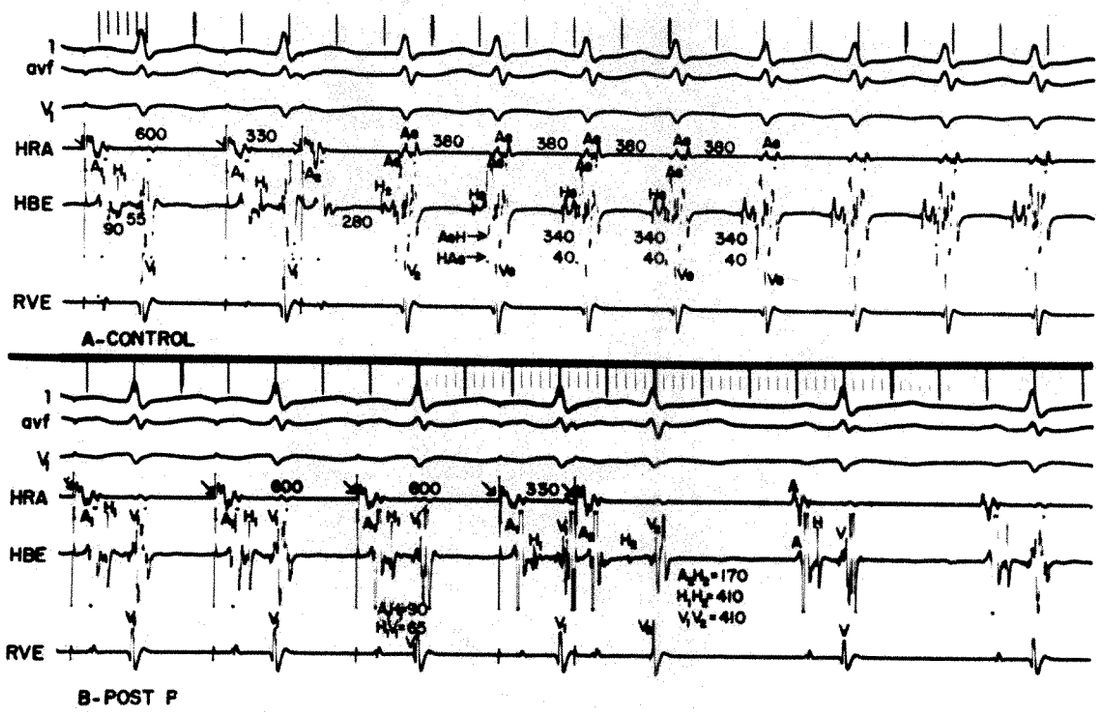

FIGURE 1. Case 1. Atrial premature stimulation during control study (**A**) and after administration of procainamide CP (**B**). **From top to bottom** in each panel: I, avf and V_1 = surface electrocardiographic leads; HRA = high right atrial electrogram; HBE = His bundle electrogram and RVE = right ventricular electrogram. **A**, at a coupling interval of 330 ms, the A_2-H_2 interval increased to 280 ms, resulting in a sudden jump in the H_1-H_2 curve (H_1-H_2 = 530 ms) with initiation of a reentrant supraventricular tachycardia. The cycle length of the tachycardia is 350 ms, the Ae-H interval is 340 ms and the H-Ae interval is 40 ms. **B**, after procainamide, at a similar coupling interval of 330 ms, the A_2-H_2 interval is 170 ms and the H_1-H_2 interval is 410 ms, both shorter than control values. Also note the inability to initiate a tachycardia.

TABLE I

Anterograde Conduction and Refractory Periods (ms) Before and After Procainamide (P)

	Case 1		Case 2		Case 3	
	Control	After P	Control	After P	Control	After P
A-H interval	90	90	75	70	75	60
H-V interval	55	65	35	40	50	55

ACL = atrial cycle length; ERP = effective refractory period; FRP = functional refractory period; NA = not attained; WB = Wenckebach block.

of the ventricular myocardium were defined as previously described.[13,14]

The presence of anterograde and retrograde discontinuous A-V nodal curves and the refractory periods of the anterograde fast and slow pathways were determined as previously described.[4-6,9]

Results

In all three patients paroxysmal supraventricular tachycardia could be induced during atrial pacing-induced A-V nodal Wenckebach periodicity or during premature atrial stimulation, or both. The reentrant nature of the tachycardia was suggested by previously established criteria.[2,3,9,15] The utilization of V-A bypass tracts in the reentrant process was excluded on the basis of the following criteria: (1) the retrograde echo (Ae) occurred simultaneously or almost simultaneously with the ventricular electrogram[8,9,15]; (2) the H-Ae/Ae-H ratio ranged from 1:2.1 to 1:8.5[8,9]; (3) ventricular stimulation during tachycardia when the His bundle was refractory did not result in atrial preexcitation[16,17]; and (4) during ventricular premature stimulation, A_2 moved out of the ventricular electrogram more or less in parallel with H_2.[8,9]

Electrophysiologic data during control studies and after procainamide are presented in Tables I and II. Serum procainamide levels were 8 to 15 mg/liter.

Case Reports

Case 1: This was a 70 year old man with recurrent paroxysmal supraventricular tachycardia. Control conduction studies during sinus rhythm revealed an A-H interval of 90 ms and an H-V interval of 55 ms. Incremental atrial pacing resulted in progressive prolongation of the A-H interval (90 to 140 ms) before the occurrence of A-V nodal Wenckebach periodicity. Atrial pacing-induced A-V nodal Wenckebach periodicity initiated sustained supraventricular tachycardia. Atrial premature stimulation studies demonstrated a discontinuous A-V nodal curve with initiation of supraventricular tachycardia during failure in anterograde fast pathway conduction. The critical A-H interval for induction of tachycardia ranged from 280 to 370 ms (Fig. 1A). The functional and effective refractory periods of the anterograde fast pathway were 405 and 340 ms and that of the anterograde slow pathway 520 and 270 ms, respectively.

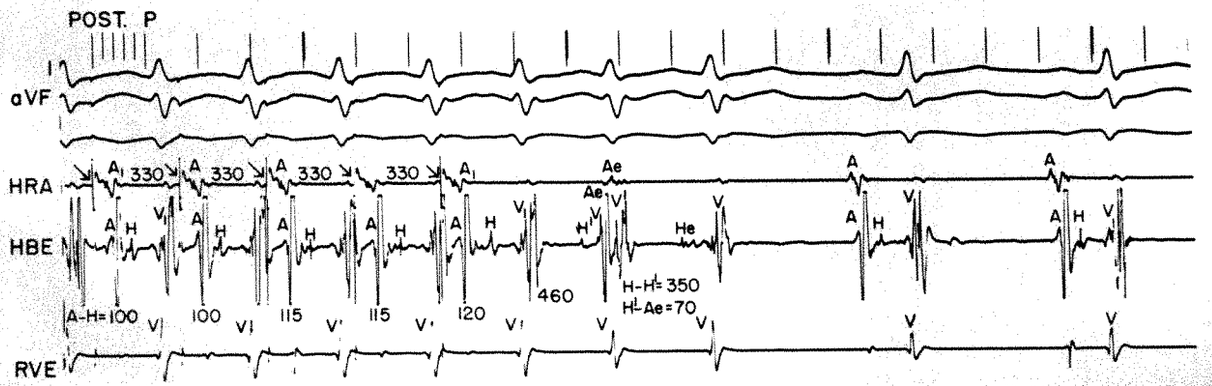

FIGURE 2. Case 1. Atrial pacing after administration of procainamide (P). Atrial pacing at a cycle length of 330 ms results in Wenckebach periodicity. After the fifth paced beat the stimulator is turned off. The last paced beat of the Wenckebach sequence results in two QRS complexes due to simultaneous conduction in both the anterograde fast (A-H = 120 ms) and anterograde slow pathway (A-H′ = 460 ms) and an echo response with an H′-Ae interval of 70 ms, which is longer than the control value (Fig. 1A). The tachycardia is not sustained because of block in the retrograde limb (that is, He-Ae block). Abbreviations as in Figure 1.

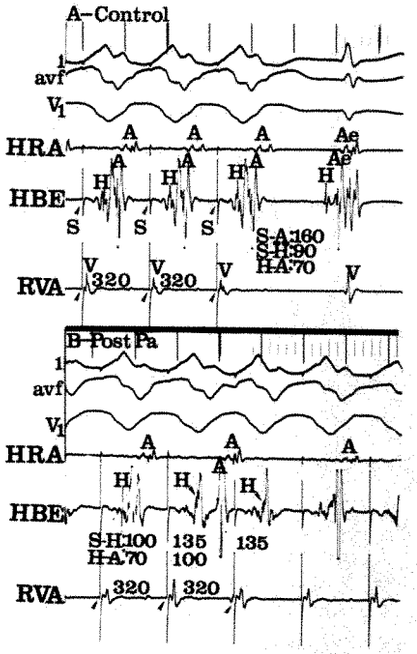

FIGURE 3. Case 1. Ventricular pacing during control study (**A**) and after administration of procainamide (**B**). **A**, ventricular pacing at a cycle length of 320 ms results in 1:1 V-A conduction. The S-H and H-A intervals measure 90 and 70 ms, respectively. **B**, ventricular pacing after procainamide (PA) at a similar cycle length as control results in a 3:2 V-A block. There is prolongation of both the S-H and H-A intervals after procainamide, but the block occurs between the H and A deflections (that is, the retrograde fast pathway). Abbreviations as in Figure 1.

After procainamide, the A-H interval during sinus rhythm measured 90 ms and the H-V interval 65 ms. Atrial pacing resulted in a smaller increase in A-H interval (90 to 130 ms) before the onset of A-V nodal Wenckebach block than that of the control period. Also, the length of the atrial pacing cycle that resulted in A-V nodal Wenckebach periodicity decreased compared with the control value (330 compared with 350 ms) (Table I). The last conducted beat of the Wenckebach sequence (Fig. 2) resulted in two QRS complexes due to simultaneous conduction in the anterograde fast (A-H = 120 ms) and anterograde slow (A-H′ = 460 ms) pathway and an echo response. The H′-Ae interval was 70 ms longer than the control value (H-Ae = 40 ms) (Fig. 1A). Also, the tachycardia was not sustained because of block in the retrograde fast pathway (that is, H-Ae block). During atrial premature stimulation, supraventricular tachycardia could not be induced because of inability to achieve a critical A_2-H_2 interval (Fig. 1B). The functional and the effective refractory periods of the anterograde fast pathway decreased (Table I) whereas that of the anterograde slow pathway could not be determined because of shortening of the effective refractory period of the anterograde fast pathway (less than 305 ms) and atrial refractoriness.

Ventricular pacing during control studies demonstrated 1:1 V-A conduction up to a pacing cycle length of 320 ms (Fig. 3A). After procainamide (Fig. 3B) at a similar ventricular pacing cycle length, 3:2 V-A block occurred because of failure in the retrograde fast pathway. There was prolongation of both S-H (retrograde His-Purkinje) and H-A (retrograde A-V nodal) intervals before block; but the block occurred between the retrograde His bundle deflection and the atrium.

During ventricular premature stimulation both S_2-H_2 and H_2-A_2 intervals increased after procainamide compared with

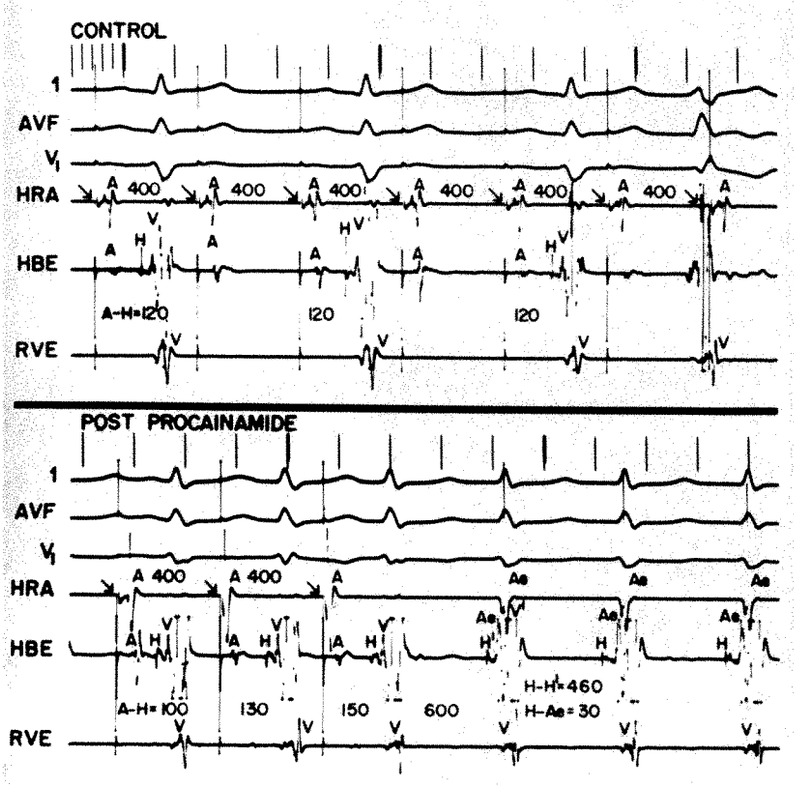

FIGURE 4. Case 2. Atrial pacing during control study and after administration of procainamide. **Upper panel,** atrial pacing during control period at a cycle length of 400 ms results in 2:1 A-V block. **Lower panel,** atrial pacing at a similar cycle length after administration of procainamide results in Wenckebach periodicity. The last paced beat of the Wenckebach sequence results in two QRS complexes due to simultaneous conduction in the anterograde fast (A-H = 150 ms) and the anterograde slow pathway (A-H′ = 600 ms) and a reentrant supraventricular tachycardia ensues.

control values, thus suggesting that the increase in the functional refractory period of the V-A conduction system (that is, the retrograde A_1-A_2) after procainamide was related to an increase in the functional refractory periods of both the His-Purkinje and retrograde A-V nodal systems (that is, the retrograde fast pathway).

Case 2: This was a 55 year old man with recurrent paroxysmal supraventricular tachycardia. Control conduction studies during sinus rhythm revealed an A-H interval of 75 ms and an H-V interval of 35 ms. Incremental atrial pacing resulted in progressive prolongation of the A-H interval (75 to 150 ms) before the occurrence of A-V nodal Wenckebach block. Neither atrial echoes nor supraventricular tachycardia resulted during atrial pacing-induced Wenckebach periodicity. Atrial premature stimulation revealed the presence of discontinuous A-V nodal curves with induction of a slow-fast tachycardia coincident with failure in the anterograde fast pathway. The critical A_2-H_2 delays required for induction of tachycardia ranged from 505 to 545 ms. The functional and effective refractory periods of the anterograde fast pathway measured 500 and 440 ms and that of the slow pathway 785 and 380 ms, respectively (Table I).

After procainamide, the A-H interval during sinus rhythm was 70 ms and the H-V interval 40 ms. In contrast to control studies when atrial pacing at a cycle length of 400 ms showed a 2:1 A-V nodal block (Fig. 4A), atrial pacing at a similar cycle length after procainamide resulted in A-V nodal Wenckebach periodicity. However, the last paced beat of the Wenckebach sequence (Fig. 4B) resulted in simultaneous conduction in both the anterograde fast (A-H-150 ms) and the anterograde slow (A-H′ = 600 ms) pathways and induction of a sustained tachycardia. As in Case 1, V-A conduction time and the functional refractory periods of the His-Purkinje and that of the V-A conduction system increased (Table II).

Case 3: This was a 72 year old man with recurrent paroxysmal supraventricular tachycardia. Control studies demonstrated an A-H interval of 75 ms and an H-V interval of 50 ms. Atrial pacing-induced A-V nodal Wenckebach periodicity resulted in a slow-fast tachycardia (Fig. 5A). Unlike the situation in Cases 1 and 2, atrial premature stimulation (cycle lengths of 600 and 500 ms) revealed a smooth A-V nodal curve with induction of tachycardia at a critical A_2-H_2 interval of 240 ms.

After procainamide, the A-H interval was 60 ms and the H-V interval 55 ms. Atrial pacing-induced A-V nodal Wenckebach periodicity (Fig. 5B) resulted in simultaneous anterograde fast (A-H = 110 ms) and anterograde slow (A-H′ = 410 ms) pathway conduction and an echo response. Supraventricular tachycardia could not be sustained because of block in the retrograde fast pathway (that is, H-Ae block). Atrial premature testing revealed a smooth A-V nodal curve as in the control study with initiation of single echoes that blocked within the retrograde fast pathway. The functional refractory period of the anterograde fast pathway decreased after procainamide and the effective refractory period of the fast pathway could not be attained (Table I).

As in Cases 1 and 2, V-A conduction time and the functional refractory period of the His-Purkinje and V-A conduction systems increased after procainamide (Table II).

Discussion

The electrophysiologic findings in our three patients indicate that the site of reentry was the region of the A-V node. Of considerable interest, however, was the observation of (1) simultaneous anterograde fast and slow pathway conduction resulting in a double ventricular response and initiation of a slow-fast echo or

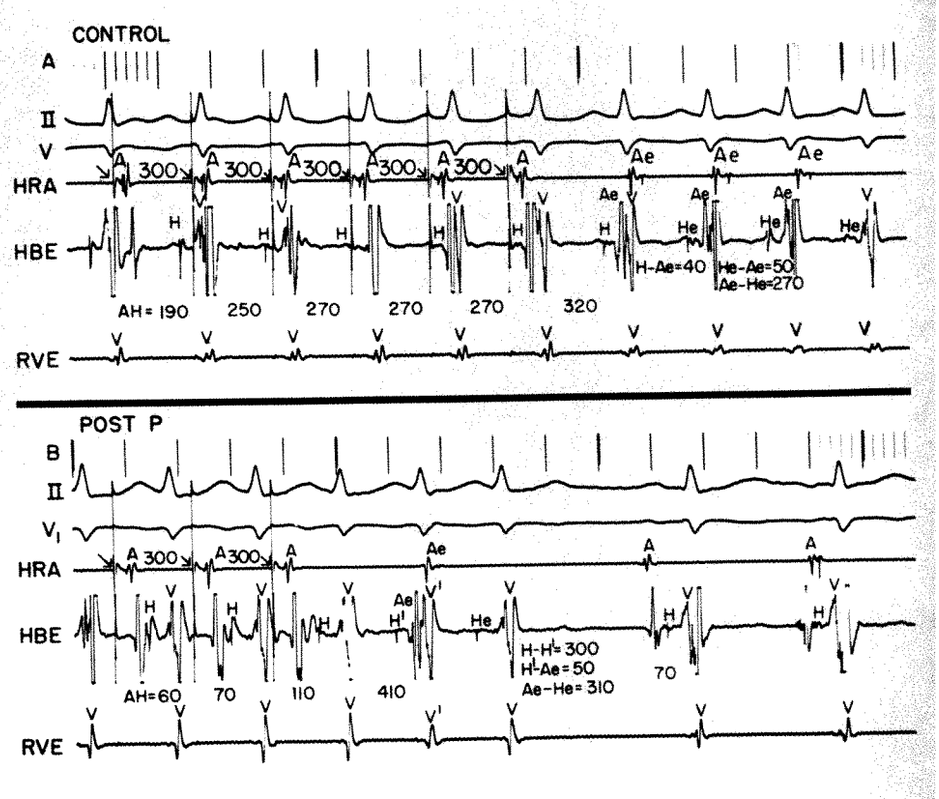

FIGURE 5. Case 3. Atrial pacing during control study (**A**) and after administration of procainamide (P) (**B**). **A**, atrial pacing at a cycle length of 300 ms results in Wenckebach periodicity with induction of a slow-fast supraventricular tachycardia. **B**, atrial pacing after procainamide (PA) at a similar cycle length also results in Wenckebach periodicity but the A-H interval is shorter than the control interval. Also, the last paced beat of a Wenckebach sequence results in a double ventricular response due to simultaneous conduction in the anterograde fast pathway (A-H = 110 ms) and anterograde slow pathway (A-H′ = 410 ms) and an echo response. The H′-Ae interval is 50 ms longer than during the control period (H-Ae = 40 ms). The tachycardia is nonsustained because of block in the retrograde fast pathway.

TABLE II

Retrograde Conduction and Refractory Periods (ms) Before and After Procainamide (P)

tachycardia, or both, after procainamide, and (2) differential effects of procainamide on the anterograde fast and retrograde fast pathways.

Simultaneous Fast and Slow Pathway Conduction

Induction of a tachycardia in patients with paroxysmal A-V nodal reentrant tachycardia is characteristically associated with either (1) failure in anterograde fast pathway conduction with resulting anterograde conduction over the slow pathway and retrograde conduction over the anterograde fast pathway; reciprocation within the anterograde slow and fast pathways is believed to be the electrophysiologic basis of a reentrant tachycardia in patients demonstrating discontinuous A-V nodal curves (dual pathways)[4–6]; or (2) achievement of a critical A-V nodal conduction delay resulting in retrograde conduction over a fast retrograde pathway.[9] Reciprocation with a slow A-V nodal pathway and a fast retrograde pathway is believed to be the electrophysiologic basis of reentrant tachycardia in patients with smooth A-V nodal curves.[9] In contrast, simultaneous anterograde fast and slow pathway conduction resulting in a slow-fast tachycardia is exceedingly rare. Wu et al.[10] reported a single case with dual A-V nodal pathways in which a slow-fast tachycardia was initiated during simultaneous fast-slow pathway conduction during pacing-induced A-V nodal Wenckebach periodicity. They suggested that pacing-induced type I block in both pathways put these pathways "out of phase" so that the distal conducting system and ventricles were able to respond to both pathways. Recently Csapo[18] reported a single case with nonreentrant paroxysmal tachycardia with simultaneous fast-slow pathway conduction. He postulated that the effective refractory period of the His-Purkinje system was shorter than the difference between fast and slow pathway conduction so that single atrial beats could initiate two ventricular responses as a result of fast and slow pathway conduction. In contrast, dual ventricular responses from a single premature stimulus are not unusual in the Wolff-Parkinson-White syndrome,[19–21] in which the presence of two distinct insulated anatomic pathways (that is, the Kent bundle and the normal A-V nodal-His-Purkinje system pathway) make the phenomenon more readily explainable.

The exceedingly rare occurrence of simultaneous anterograde fast and slow pathway conduction in the region of the A-V node may be related to the following: (1) close proximity of the two functional or anatomic A-V nodal pathways; (2) incomplete insulation of the two pathways with crossover of the impulse to the slow pathway during anterograde fast pathway conduction so that the anterograde impulse traversing down the slow pathway finds the latter refractory at its caudal end and vice-versa; and (3) refractoriness of the His bundle after its excitation by the anterograde fast pathway.

Effect of procainamide: In our patients simultaneous fast and slow pathway conduction with induction of a slow-fast tachycardia was reproducibly observed only after the administration of procainamide and only during atrial pacing at rates that resulted in A-V nodal Wenckebach periodicity. Furthermore the stimulation sequences utilized during control studies were identical to those used after procainamide. This finding suggests that procainamide altered conduction and refractoriness of both pathways so that simultaneous conduction could occur resulting in a double ventricular response and a slow-fast tachycardia. Although the precise effects of procainamide that created the necessary milieu for simultaneous anterograde fast and slow pathway conduction is uncertain, the following three hypotheses can be offered (Fig. 6):

1. A greater enhancement of anterograde fast pathway conduction or shortening of refractoriness of the anterograde fast pathway relative to that of the anterograde slow pathway, or both, resulted in Wenckebach periodicity in both pathways. Thus, although Wenckebach periodicity was simultaneously occurring in the slow pathway, it was not manifested because of the faster anterograde fast pathway conduction. Only when the stimulator was turned off did conduction in the slow pathway become manifest resulting in a double ventricular response (Fig. 6A). Enhanced conduction within the anterograde pathway and a decrease in refractori-

ness after procainamide is supported by the observation of a smaller increase in the A-H interval before development of A-V nodal Wenckebach block compared with the control value, a shorter cycle length for Wenckebach periodicity compared with the control value and shortening of the functional and effective refractory periods of the anterograde fast pathway.

2. Complete insulation of the two pathways is produced by procainamide (Fig. 6B). However, if this hypothesis were true, then one would have expected simultaneous conduction during atrial premature stimulation.

3. Conduction shifts from the anterograde fast pathway to the anterograde slow pathway[18] (Fig. 6C). Although this seems a distinct possibility, the inability of the electrode catheter technique to assess the point of turnaround of the impulse within the A-V node (that is, the distal common pathway) makes this hypothesis difficult to prove or disprove.

The induction of an echo response through the fast pathway during simultaneous anterograde fast and slow pathway conduction may be related to (1) sufficient delay in the slow pathway enabling the anterograde fast pathway to recover excitability so that retrograde conduction could occur through the anterograde fast pathway, or (2) selective utilization of a retrograde fast pathway different from the anterograde fast pathway.

Differential Effects of Procainamide on Anterograde and Retrograde Fast Pathways

Effect on anterograde fast pathway: Procainamide demonstrated differential effects on the anterograde fast and retrograde fast pathways in all three patients. Enhanced conduction and decreased refractoriness of the anterograde fast pathway is supported by the following findings: (1) a relatively smaller decrease in the A-H interval before development of A-V nodal Wenckebach block, and (2) a decrease in both the functional and effective refractory periods of the anterograde fast pathway. In Case 1 the effective refractory period of the anterograde fast pathway could not be attained following procainamide and was probably less than the effective refractory period of the atrium. Also the inability to demonstrate a discontinuous A-V nodal curve after procainamide in this patient was obviously related to marked shortening of the effective refractory period of the anterograde fast pathway so that a discontinuous A-V nodal curve during control was converted to a smooth A-V nodal curve after administration of procainamide. In a previous study on the effects of procainamide in A-V nodal reentrant tachycardia Wu et al.[22] found that this drug had no significant effects on the anterograde fast pathway. However, their data indicate that procainamide decreased the effective refractory period of the fast pathway in four of eight patients in whom dual pathway curves were observed both during the control period and after administration of procainamide. Furthermore, in another four patients they could not assess the effective refractory period of the fast pathway because after procainamide dual pathway curves were converted to smooth A-V nodal curves. It is likely that the conversion of a dual pathway curve to a smooth curve was related to the shortening of the effective refractory period of the fast pathway, the attainment of which was limited by atrial refractoriness as in our Case 1. We were able to assess refractoriness of the anterograde slow pathway only in Patient 2, in whom procainamide decreased both the functional and effective refractory periods of the slow pathway. However, enhanced slow pathway conduction is suggested by shorter cycle lengths resulting in A-V nodal Wenckebach block. These effects of procainamide on the anterograde fast and slow pathways are in all likelihood related to the vagolytic effects of the drug.[23,24]

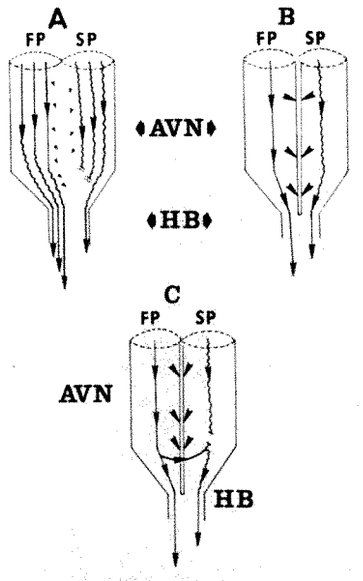

FIGURE 6. Schematic representation of the mechanisms for simultaneous anterograde fast (FP) and slow (SP) pathway conduction after procainamide. **A**, simultaneous Wenckebach periodicity within the fast and slow pathways. The first two impulses down the slow pathway are not manifest because of more rapid fast pathway conduction. However, the third impulse down the slow pathway becomes manifest after the third impulse down the fast pathway, but only when the stimulator is turned off. **B**, simultaneous conduction due to insulation of the fast and slow pathways. **C**, crossover of the impulse from the fast to the slow pathway during fast pathway conduction, resulting in a dual ventricular response. For further explanation see text. AVN = atrioventricular node; HB = His bundle.

Effect on retrograde fast pathway: In contrast to the effects of procainamide on the anterograde fast pathway, the drug had a depressant effect on the retrograde fast pathway, as suggested by the following: (1) the occurrence of V-A block at longer cycle lengths than control values; (2) lengthening of the functional refractory period of the retrograde fast pathway, as suggested by an increase in the functional refractory period of the V-A conduction system; and (3) inability to sustain tachycardia in Cases 1 and 3 because of block in the retrograde fast pathway. These effects of procainamide are probably related to its direct depressant effects on the retrograde fast pathway and are in agreement with the observations of Wu et al.[22]

Clinical implications: The diametically opposite effects of procainamide on the anterograde fast pathway (enhanced conduction and shortening of refractoriness) and retrograde fast pathway (depressed conduction and lengthening of refractoriness) have important implications. These include: (1) The retrograde fast pathway is physiologically and perhaps anatomically distinct from the anterograde fast pathway, and (2) the drug response of the retrograde fast pathway resembles that of Purkinje muscle whereas the response of the anterograde fast pathway resembles that of the A-V node. Previous studies on the effects of digitalis[7,9] and verapamil[25] on the retrograde fast pathway support these conclusions.

Take a close look at Compu-Scan™ The future in Holter Technology

inaccuracy of first and ɔnd generation Holter ɨpic Counters is legend. ıe analog-based voltage ɜsurements have proven so ːcurate in fact that most s preferred to disbelieve the ɔpic counters and count on r own visual identification of ıormal beats.

ɹt now there's Compu-scan ıe eye that never looks away. ɐw generation in Holter ɜms, Compu-scan utilizes icrocomputer to build in nory an average or typical ɲplex for each patient. "normal" is constantly up- ɐd as the patient's activity nges. In microseconds, computer makes all of the calculations on each new QRS complex that the human mind would take minutes to determine. It's a quantum leap ahead in ectopic beat recognition . . . both in speed and accuracy.

- Only Compu-scan can scan tapes produced on virtually any Holter recorder, cassette, reel to reel, direct recording or FM.
- The large 15" monitor provides over a minute of ECG on the screen at one time, plus up to 512 seconds in memory.
- Complete summary reports and graphics are produced on Compu-scan's high speed line printer while summary graphs and reports are displayed in color on the Color-graphics display.
- Modular in design, Compu-scan can be incorporated into your facility a step at a time as your needs dictate. Take a close look at Compu-scan and you'll see the future in Holter technology.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Yorke Medical Books
666 Fifth Avenue, New York, N.Y. 10103

Aldactone®
(spironolactone)

WARNING
Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats (see Warnings). Aldactone should be used only in those conditions described under Indications. Unnecessary use of this drug should be avoided.

Indications: *Diagnosis and treatment of primary hyperaldosteronism. Essential hypertension, edema of congestive heart failure and the nephrotic syndrome, when other measures are considered inappropriate. Cirrhosis of the liver accompanied by edema and/or ascites. Hypokalemia.*

Contraindications: *Anuria, acute renal insufficiency, significant impairment of renal function, or hyperkalemia.*

Warnings: *Excessive potassium intake may cause hyperkalemia. Potassium supplements should not be given with Aldactone. Do not administer concurrently with other potassium-sparing diuretics.*

Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. In one study using 25, 75, and 250 times the usual daily human dose (2 mg./kg.) there was a statistically significant dose-related increase in benign adenomas of the thyroid and testes. In female rats there was a statistically significant increase in malignant mammary tumors at the mid-dose only. In male rats there was a dose-related increase in proliferative changes in the liver. At the highest dosage level (500 mg./kg.) the range of effects included hepatocytomegaly, hyperplastic nodules and hepatocellular carcinoma; the last was not statistically significant.

Precautions: *Patients should be carefully evaluated for possible disturbances of fluid and electrolyte balance. Hyperkalemia may occur in patients with impaired renal function or excessive potassium intake and can cause cardiac irregularities which may be fatal. Hyponatremia may be caused or aggravated, especially when Aldactone is administered in combination with other diuretics. Transient elevation of BUN and/or mild acidosis may occur. Aldactone potentiates the effect of other diuretics or antihypertensive agents, particularly ganglionic blocking agents; therefore the dosage of such drugs should be reduced by at least 50 percent when adding Aldactone. Gynecomastia may develop and in rare instances some breast enlargement may persist. Vascular responsiveness to norepinephrine may be reduced.*

Spironolactone may cross the placental barrier. Use in pregnant women requires that the anticipated benefit be weighed against possible hazard to the fetus. Breast feeding should be discontinued when Aldactone is being used.

Adverse Reactions: *Gynecomastia is observed not infrequently. Gastrointestinal symptoms including cramping and diarrhea, drowsiness, lethargy, headache, maculopapular or erythematous cutaneous eruptions, urticaria, mental confusion, drug fever, ataxia, inability to achieve or maintain erection, irregular menses or amenorrhea, postmenopausal bleeding, hirsutism and deepening of the voice. Carcinoma of the breast has been reported but a cause-and-effect relationship has not been established. Adverse reactions are usually reversible upon discontinuation of the drug.*

Dosage and Administration

For primary hyperaldosteronism: *400 mg. daily for three to four weeks (long test), or for four days (short test). For preparation for surgery or for long-term maintenance therapy, 100 to 400 mg. daily.*

For edema in adults: *Initial daily dosage is 100 mg. in divided doses but may range from 25 to 200 mg. daily. If after five days an adequate diuretic response has not occurred, a second diuretic which acts more proximally in the renal tubule may be added. The dosage of Aldactone should remain unchanged when other diuretic therapy is added.*

For edema in children: *Initial daily dosage should provide approximately 1.5 mg. per pound of body weight (3.3 mg./kg.) in divided doses.*

For essential hypertension: *Initial adult daily dosage of 50 to 100 mg. in divided doses, alone or with diuretics which act more proximally in the renal tubule, or with other antihypertensive agents. Continue treatment for at least two weeks since maximal response may not occur before this time. Adjust subsequent dosage according to patient response.*

For hypokalemia: *25 to 100 mg. daily in divided doses.*

When other measures are considered inadequate or inappropriate

Aldactone®
(spironolactone 25 mg)

The uncomplicator in CHF therapy

"Round-the-house" edema, electrolyte washout, subtle secondary volume buildup

☑ *Aldactone, an effective diuretic in its own right, also enhances the efficacy of other diuretic agents.*

☑ *The unique potassium-regulating mechanism of Aldactone can prevent hypokalemia with limited risk of hyperkalemia. This helps protect your patient from digitalis-induced arrhythmias.*

☑ *Unlike other potassium-sparers, Aldactone specifically antagonizes aldosterone, thereby mitigating secondary volume buildup.*

For these reasons, Aldactone is a valuable adjunct in the treatment of CHF.

***Limitations to Consider**: Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. Thus, Aldactone should be prescribed only when other measures are considered inadequate or inappropriate. (See boxed warning and* Warnings *section of Aldactone prescribing information.)*

Before prescribing, please consult the complete prescribing information, a brief summary of which appears on the preceding page.

The Agony and the Ecstasy and the Agony of installing your own Holter System.

The Agony.

Seemed like a good idea. Your very own Holter System. Right there in the hospital. Then you shopped around.

What you found was an easy way to get lost. Umpteen totally different models. Endless claims and testimonials. And more miracles of modern technology than there are gas guzzlers on America's used car lots. And not one decent, long-running track record in the bunch.

The Ecstasy.

But you hung in there. Took some chances and made a few guesses. And chose the spiffiest new model with the most splendiferous features you could find. How could it ever be obsolete? Buttons by the dozen. Dials, screens, and keyboards. And more switches, levers, lights, meters, buzzers and whistles than you'll ever know what to do with.

You were *so* happy when it arrived.

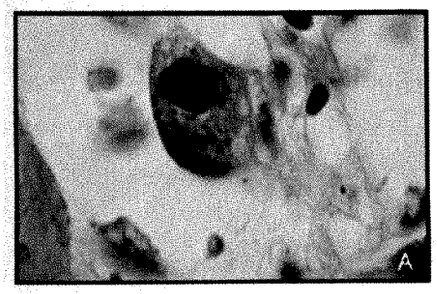
And the Agony.

Now all you had to do was find a bit of space for it—well, maybe a little more. And train a technician or two to operate it—if you could find them.

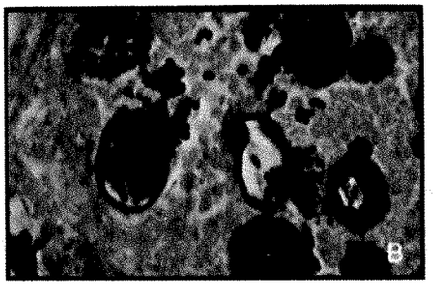
Then there was that financing (what financing?). Maybe up to seventy thousand dollars worth? And the interest—at rates known as usury in Biblical times. Oh, and salaries for the nurses and technicians.

Not to mention maintenance. The down time. What to *do* when it's down. What to do when the *staff* is down, or on strike, or..., or whatever!

The Alternative.



After all this, one begins to realize that what was really wanted was, not gadgets, gizmos, lights, dials, and whistles—but *information*. Accurate data. Clearly reported. The kind of well documented, intelligently presented, quantitated data you get with every Clinical Data LCG Report.



Even if you've seen one of Clinical Data's LCG Reports, you haven't really seen one of Clinical Data's *new* LCG Reports. We've made the best even better. Call or write. We'll send you one.

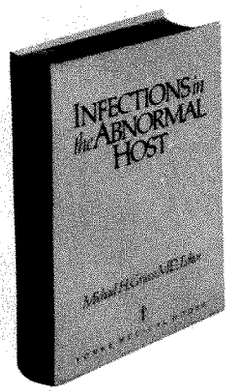
Paintings by Jackson Pollock?

Good guess for a layman. But *to you* these are the enemy. They are Cytomegalovirus gastritis (A) Disseminated coccidioidomycosis (B) and Strongyloides stercoralis filariform larva (C) . . . infections which demand special care when they strike patients with pre-existing illnesses and deficiencies. They are among the many discussed in . . .

INFECTIONS
IN THE ABNORMAL HOST



Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color

Now at your fingertips . . . for instant reference . . . for rewarding study . . . the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which attack patients under treatment for

- Diabetes
- Alcoholism
- Cancer
- Drug Addiction
- Rheumatic Disease
- Uremia
- Pulmonary Disease
- Hepatic Insufficiency
- Allograft Transplantation, etc., etc.

Infections in the Abnormal Host brings together in one giant encyclopedic volume, over 1,000 pages, the guidance of a specialist team whose collaboration began in the 1960's. In 36 revealing chapters they review the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

A detailed indexing system gives you instant access to every diagnostic procedure, every treatment in the book. Study the entire book and you will gain priceless knowledge of an important and complex field. Consult it as the need arises, and it will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Try this important new reference book 30 days free

An essential manual for practitioners . . . a long-needed text for students. Over 1,000 pages. 7" x 10". Clothbound. 147 illustrations including 78 full-color photos. Completely indexed. $65.00, plus shipping.

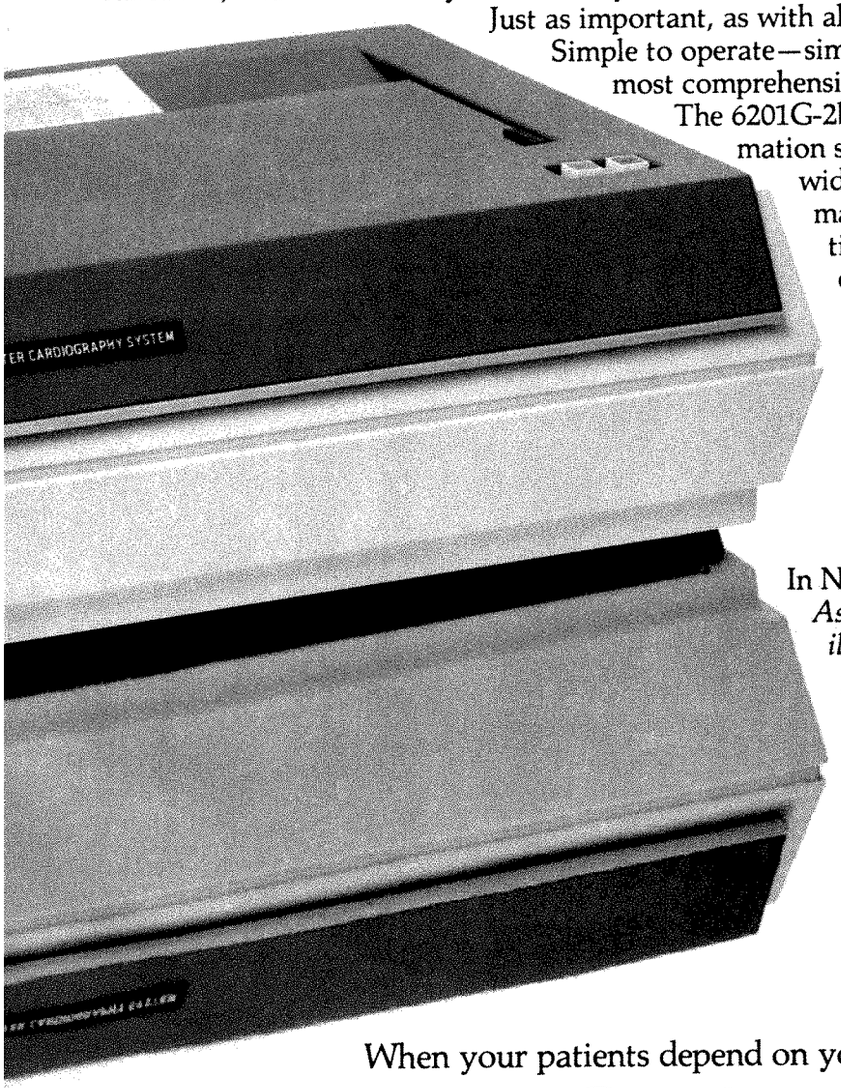
SOPHISTICATED
SIMPLE

AND DELIVERABLE.

The ICR 6201G-2b: an information breakthrough in Holter cardiography.

A breakthrough in Holter cardiography doesn't do medicine a bit of good if it's still on the drawing board. At ICR, not only can *every* Holter system we make be delivered quickly and dependably, but each is also the result of an aggressive clinical evaluation program.



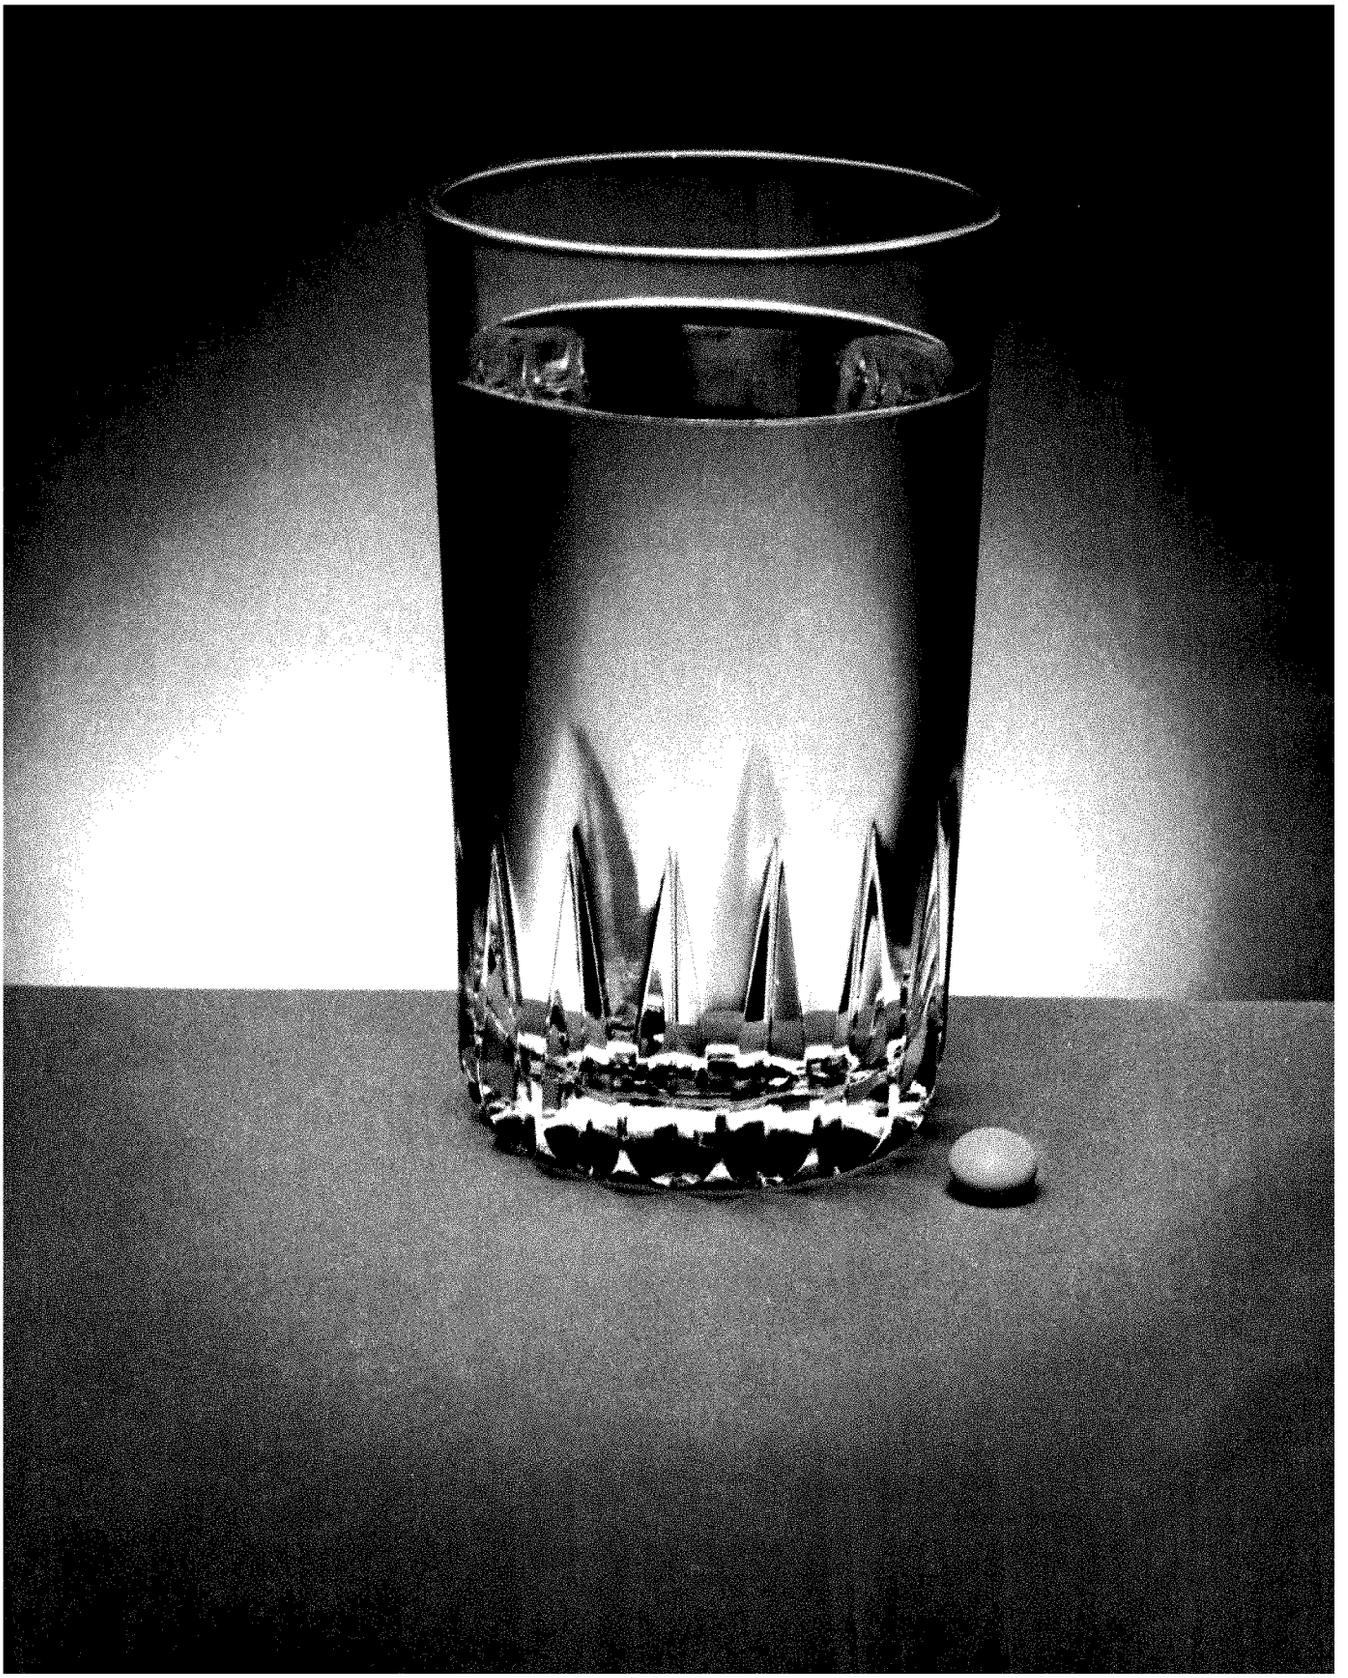
For instance, our new 6201G-2b Holter system is *ready right now for day-to-day use.* It's the most sophisticated ever developed.

Sophisticated in terms of its microprocessor design, its superior range of scanning functions, and its sensitivity to and analyses of cardiac information.

Just as important, as with all ICR Holter systems, *it's simple.* Simple to operate—simple to upgrade—and simply the most comprehensive system available.

The 6201G-2b allows you to choose the information summary format you prefer from a wide range of options. This flexibility makes the 6201G-2b the most practical and powerful Holter system ever developed.

ICR makes a full range of Holter systems to meet virtually any diagnostic or budget consideration. We build these systems to *your exact needs.*



Call toll-free
1-(800)-448-1675.

In New York, call collect: (315) 437-7291.

Ask for a copy of our beautifully illustrated "Failsafe Holter Hook-up" poster and more information on the wide range of ICR Holter systems. Or write: Instruments for Cardiac Research, 6057 Corporate Drive, East Syracuse, N.Y. 13057, U.S.A.

When your patients depend on you, depend on our technology.

Instruments for Cardiac Research, Inc.

THEY ONLY TASTE THE WATER

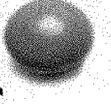
The plain truth about potassium supplements—many patients just don't take them

Many patients just can't take liquid or effervescent preparations day after day, no matter how they are diluted or the taste is disguised. Thus, in the long run, they fail to get the potassium they need.

Helps solve compliance problems two ways

KAON-CL TABS have no taste or after-taste, no matter how long they are taken.

KAON-CL TABS are easy to remember, with a simple t.i.d. dosage schedule and ready portability.



Minimizes likelihood of GI complications

Each KAON-CL TABS tablet provides 500 mg KCl (6.7 mEq) in a special wax matrix which controls release of potassium chloride over several hours. Thus, the likelihood of high localized concentrations of KCl in the GI tract is minimized. The reported frequency of GI lesions with wax-matrix tablets is less than one per 100,000 patient-years. There have been only two equivocal cases of GI bleeding reported with KAON-CL TABS to date and no reports of small bowel stenosis or ulceration. However, clinical experience is insufficient at this time to indicate that the incidence is other than the stated numerical ratio.

Patients stay on

KAON-CL TABS®

(potassium chloride) Controlled Release Tablets

For summary of prescribing information, please see following page.

A121

Controlled Release Tablets

Description: Kaon-Cl Tabs is a sugar coated (not enteric-coated) tablet containing 500 mg potassium chloride (equivalent to 6.7 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns. adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: *Hyperkalemia*—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon-Cl Tabs (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon-Cl Tabs should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100, 250 and 1000.

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Cer Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visi Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—inde *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons v this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced b pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, th book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form th pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints bu at the same time evaluating relative strengths and weaknesse of each observation and hypothesis. There is brought a wisd here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman the Department of Medicine, The University of Alabama in Birmi ham, and Physician-in-Chief, University of Alabama Hospitals.

PHO/GAMMA® LEM® with stress table

PHO/GAMMA® LEM®

IMAGE MAGNIFIER/ROTATOR

PHO/GAMMA® LFOV™

GAMMA/COR® RCG

The Pho/Gamma® LEM Scintillation Camera provides high resolution, high count rate nuclear medicine imaging capability at the patient's bedside. The LEM is available with power assist or optional power drive and is suitable for mobile applications or use in stationary settings such as in stress testing laboratories.

The Image Magnifier/Rotator allows magnification (up to 2.75 times normal size) of camera data prior to digitizing and display. Magnification aids in visualizing small organs imaged with a large field of view camera. The Image Rotator provides 360° rotation of camera data to allow operator chosen orientation of clinical studies.

The Pho/Gamma® LFOV™ Scintillation Camera is a high performance LFOV Detector, integrated with a microprocessor-based Standard Console (Scintiview™ with Micro Dot Imager™) that provides cardiac analysis and processing with optional ECAP and ACAP programs.

ZLC provides uniformity and linearity correction in a manner which will not distort quantitative camera data. The demanding camera requirements necessary to perform quantitative nuclear cardiology are met with ZLC.

The Gamma/Cor® RCG is a lightweight, highly mobile cardiac system which offers a unique direct method for rapid, repeatable assessment of left ventricular ejection fraction in a minimally invasive, safe manner right at the patient's bedside. The Gamma/Cor also provides assessment of other cardiac parameters such as cardiac output.

A HISTORY OF PERFORMANCE... A COMMITMENT TO THE FUTURE.

SIEMENS

PRINTED IN U.S.A.

"EJECTION FRACTION CALCULATION START TO STOP IN 3 MINUTES OR LESS (ECAP)"

Ejection fraction processing takes 3 minutes or less using Scintiview's™ microprocessor based electronics, English language pushbutton operation and ECAP (Extended Cardiac Analysis Package).

ECAP features extended wall motion analysis via "stroke volume", "ejection fraction" and "paradox" images, 128 x 128 gated acquisition for myocardial images, and sequential acquisition and processing "batch" of multi-gated blood pool studies.

"DEFINE LEFT VENTRICULAR BORDER WITHOUT OPERATOR INTERVENTION (ACAP)"

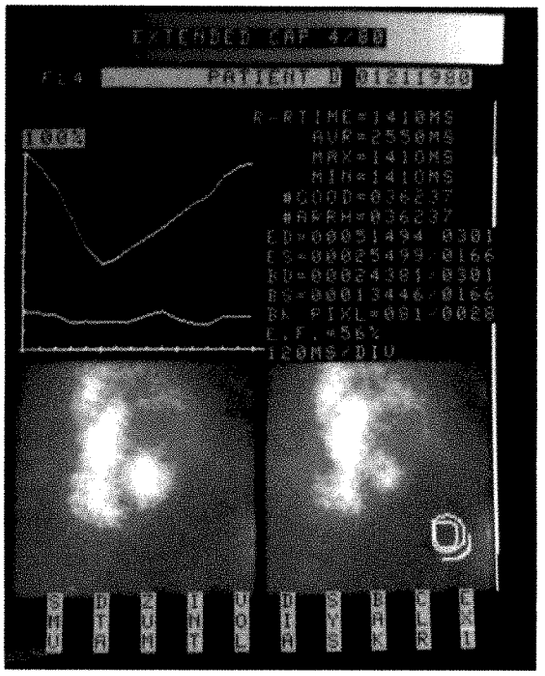
ACAP, the third in a series of new cardiac performance packages, provides complete and automatic definition of the left ventricular border in each frame of a multi-gated study, without operator intervention. ACAP also includes all of ECAP's features.

Acquisition and Processing Features

Operator selection of study termination parameters (memory full, time). For intervention studies, up to eight sequential multi-gated blood pool studies may be acquired. Rapid analysis of ventricular parameters can be obtained conveniently by use of lite pen or automatically via an advanced edge detection algorithm requiring little or no operator intervention. Storage of R-R time intervals, ejection fraction data, volume curve and regions of interest is permitted.

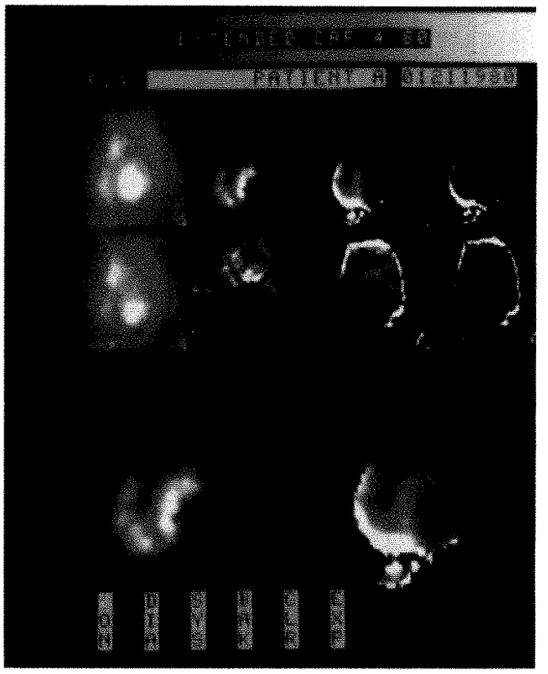
Myocardial Gated Imagery

Stop action viewing of technetium pyrophosphate infarct images or Thallium-201 perfusion images is provided in a 128 x 128 matrix. 100 millisecond time intervals provide motion deblurring without excessively prolonged study time. Thallium-201 four frame 128 x 128 gated images may be displayed in cine mode for visualization of myocardial thickening.

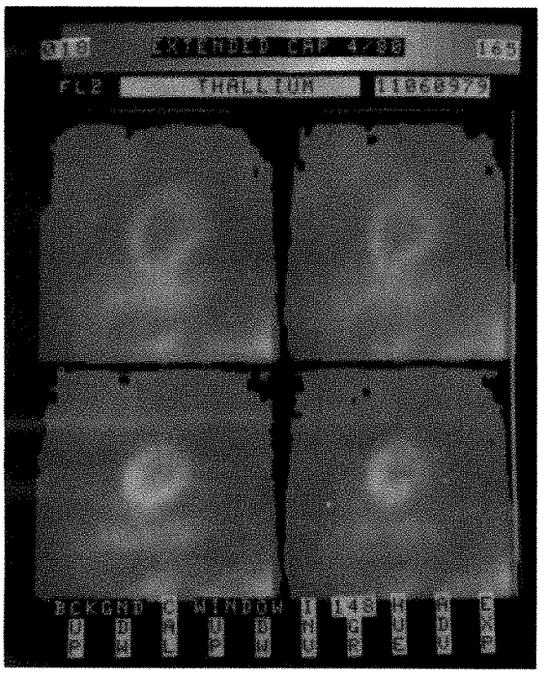


Extended Wall Motion Analysis

Display of regional volume changes on a pixel by pixel basis is provided in a static gray scale format via "functional" images. Analysis of dyskinetic wall motion is obtained by use of the "paradox" image. Overlap of the diastolic and systolic borders over the "stroke volume" image are possible to aid in ROI assignment over the left ventricle.

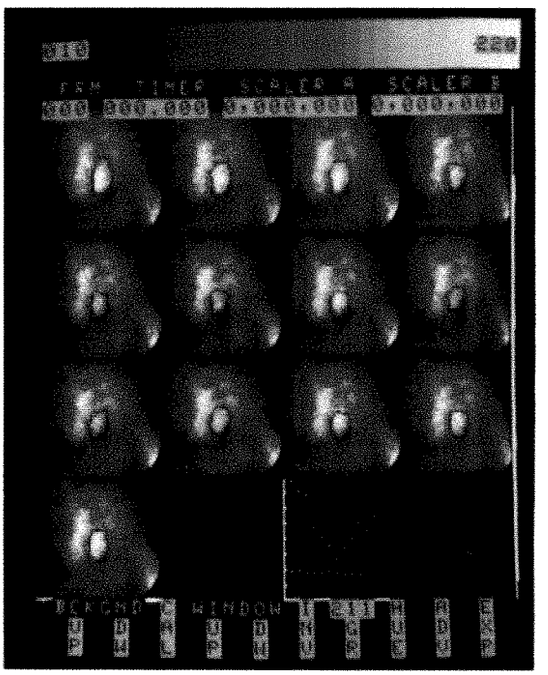


ECAP and ACAP are part of our commitment to nuclear cardiology. For complete information on ECAP, ACAP, and/or our line of nuclear cardiology products, Pho/Gamma® LEM®, Pho/Gamma SFOV and LFOV™, Pho/Con®, Gamma/Cor®, Slant Hole Collimator, or Image Magnifier-Rotator, call or write today.



SIEMENS GAMMASONICS, INC.
Nuclear Medical Division
2000 Nuclear Drive
Des Plaines, IL 60018
Telephone 312/635-3100

Multi-gated blood pool studies can be acquired in either single or sequential modes with the ejection fraction data displayed for one study or up to eight stress or intervention studies at once.



Regional wall motion changes within the heart can be displayed through "stroke volume" and "ejection fraction" images. Additionally paradox images enhance the diagnosis of dyskinetic myocardial segments for complete cardiac analysis.

A gated 128 by 128 mode reduces motion blur in myocardial images without significantly prolonging study time.

The ACAP Program provides an automated wall detection method for outlining left ventricular borders and provides accurate, reproducible left ventricular ejection fractions.

Systemic Arterial Hypertension Associated With Cardiac Surgery

FAWZY G. ESTAFANOUS, MD, FACC
ROBERT C. TARAZI, MD, FACC

Cleveland, Ohio

Significant hypertension can develop in 15 to 40 percent of patients undergoing various types of cardiac surgery. These hypertensive episodes can occur at almost any time before, during or after open or closed chest operations. The various hypertensions encountered in this context do not form a homogeneous entity; they are not due to the same causes and do not necessarily develop by the same mechanisms. Their frequency and seriousness have been demonstrated by reports from many centers: hence, the urgent need for accurate definition of their various types to allow correct identification and therapy. A classification based on well defined clinical events is therefore proposed and possible mechanisms for the more common types of hypertension are reviewed. Prophylactic measures include reassurance, attention to details of anesthesia and maintenance of preoperative antihypertensive therapy when indicated; for patients with coronary artery disease, preventive nitrate therapy as well as prompt attention to chest pain is essential. Both general and specific antihypertensive measures to control the more common types of hypertension complicating cardiac surgery are outlined.

Since its initial description in 1973,[1] hypertension has been increasingly recognized as a frequent complication of coronary bypass surgery[2–4] and has been reported to occur in 30 to 50 percent of cases.[1–3] The complication can be quite serious,[1,5,6] and the final outcome depends on the rapidity of diagnosis and early initiation of adequate therapy.[1,7] Apart from defining a specific problem, clinical studies of this syndrome have also created heightened sensitivity to hypertension in cardiac surgery and increased awareness that hypotension is not the only danger to be guarded against.[2,7]

As reports and studies from various centers rapidly increase, a more exact definition of the problem is needed to avoid confusion, especially because hypertension associated with cardiac surgery is not limited to coronary bypass grafting or to the postoperative period.[8–11] Pressor factors abound in the situation surrounding open heart surgery[1,11,12]; hence, hypertension may occur at different periods in relation to the procedure, as well as from various causes or mechanisms. The many mechanisms that can be involved in different circumstances are illustrated by current discussions about pathophysiologic characteristics and various approaches to therapy.[1–4,12–14] This multiplicity is hardly surprising because systemic arterial pressure is determined by a highly integrated cardiovascular control system. The multiple variables involved in this system[15] can all be affected by anesthesia, surgery and cardiopulmonary bypass: hence, the predisposition to potentially damaging hypotension or hypertension during major surgical interventions.

Classification

Serious hypertension can occur with any type of cardiac surgery and at practically any time, from the moment of wheeling the patient to the surgical unit to a few months after cardiac valve replacement.[3,7,16] A classification based on cause or specific mechanism would be both dif-

From the Department of Cardio-Thoracic Anesthesia and the Research Division, The Cleveland Clinic Foundation, Cleveland, Ohio. ficult and premature because of the current controversy surrounding the subject and of the many factors involved. In contrast, a classification based on well defined clinical events such as timing in relation to surgery would allow an acceptable definition of the hypertension that is being considered and, thus, comparison of reports from different observers.

The hypertension occurring during endotracheal intubation or during cardiopulmonary bypass develops in a setting different from that which occurs during arousal from anesthesia. Grouping all these types of hypertension together, as some reports have done, would either prejudge the issue of causation or result in an unwieldly heterogenous entity (Table I).

The definition of levels considered as hypertensive episodes has varied among published reports. Estafanous et al.,[1] in their original description, defined a hypertensive episode as a rise in blood pressure to levels above 160/100 mm Hg in previously normotensive patients or an increase of more than 30 mm Hg (either systolic or diastolic) above preoperative levels in hypertensive patients. Elevations rapidly controlled with sedation or by increasing the level of anesthesia have been discounted in most studies[1–3]; this does not mean that they should not be attended to carefully.

Preoperative Acute Hypertension

Chaptal et al.[17] stressed the frequency of acute increases in arterial pressure in the preanesthetic period; Roberts et al.[2] found such increases in 15 percent of their patients. Obvious reasons for these changes include inadequate premedication, anxiety and discomfort from various interviews, injections or tests. More important, a sudden rise of pressure in patients with coronary insufficiency can precipitate angina pectoris and trigger a vicious cycle of hypertension and chest pain.[18,19] Adrenergic hyperactivity was documented by a shortened Q-S_2 interval in many patients before saphenous vein bypass grafting; this interval measured preoperatively was, in fact, significantly shorter in those who later had a perioperative infarction.[20] Premedication to provide adequate sedation and analgesia is obviously needed; the routine use of nitrites ("nitroglycerin paste") as a component of premedication might also help prevent a paroxysm of hypertension secondary to coronary insufficiency.

Role of preoperative antihypertensive agents: Of particular importance in this context is careful preoperative monitoring of arterial pressure. Hypertension can develop before the chest pain of coronary insufficiency.[18] Rapid increases in blood pressure could also be due to cessation of antihypertensive therapy before surgery.[21] Better knowledge of pharmacology and circulatory control mechanisms has modified that practice, which was the rule until the early 1960s[22]; each case and each drug must be considered in its own right. The tendency today would be to avoid cessation of antihypertensive therapy to prevent the burden of a rising pressure on the heart and atherosclerotic vessels.[22,23] Because newer antihypertensive agents have a much shorter duration of action than that of older drugs such as reserpine and guanethidine, the return of arterial pressure to hypertensive levels could occur rapidly. Moreover, "rebound" adrenergic hyperactivity has been described after abrupt cessation of clonidine[24] and propranolol[25]; the clinical findings are not restricted to an increase in pressure but include a recognized syndrome of restlessness, tachycardia and a slight flush suggestive of an autonomic crisis. In this situation the possible dangers to a patient with cardiac or coronary disease are obvious. The time has therefore come for a reevaluation of rules regarding beta adrenergic blockade and cardiac surgery. It is now our practice to maintain beta adrenergic blocking agents until the time of surgery. In our opinion, the advantages of decreased myocardial oxygen consumption obtained by controlling blood pressure and slowing heart rate outweigh the risk of possible hypotension during surgery, a risk that can easily be managed.

In summary, careful appraisal of antihypertensive therapy is an essential step in preparation for surgery. Rules regarding maintenance or discontinuance of treatment must be individualized with preference given, if possible, to continued control of arterial pressure by relatively short-acting agents that interfere as little as possible with baroreceptor reflexes.

TABLE I

Hypertension Associated With Cardiac Surgery

Preoperative
Anxiety situation, anginal crisis, and other incidences
Discontinuance of antihypertensive therapy
"Rebound" from beta blocking agents in patients with coronary artery disease
Intraoperative
Induction of anesthesia
Specific drugs
Hypertension due to tracheal intubation and nasopharyngeal, urethral or rectal manipulation
Precardiopulmonary bypass (during sternotomy and chest retraction)
Cardiopulmonary bypass
Postcardiopulmonary bypass (during surgery)
Postoperative
Early—within 2 hours
Obvious cause: hypoxia, hypercarbia, ventilatory difficulties, hypothermia shivering, arousal from anesthesia
With no obvious cause: after myocardial revascularization; less frequently after valve replacement; early (Sealy type I) hypertension after resection of aortic coarctation
Intermediate—12 to 36 hours after surgery: Sealy type II after repair of aortic coarctation
Late—weeks to months: after aortic valve replacement by homografts

Intraoperative Hypertension

Induction of anesthesia: This procedure constitutes one of the more serious threats to circulatory stability.[22] The dangers of hypotension and its management have been stressed in the past.[26–28] In that context, the relation of sympathetic activity of anesthetic agents, cardiac performance and vascular control is of particular importance. The contractility of the isolated heart is severely reduced by most anesthetic agents,[29] but this reduction is counterbalanced in intact organisms by reflex sympathetic activity.[22] Undue depression of adrenergic activity is undesirable in diseased hearts be-

ause they are more dependent than normal on this drive for adequate performance.[30] A case was therefore made for the discontinuance preoperatively of drugs such as some antihypertensive agents that could interfere with autonomic reflexes. However, hypertension during surgery can be equally threatening in patients with heart disease, particularly those with coronary artery disease. Although paroxysmal increases in pressure are not necessarily prevented by maintaining antihypertensive therapy, they might be exaggerated by its untimely discontinuance.[2,21] In that context, coronary artery disease adds another complication because of the potential imbalance between a restricted myocardial oxygen supply and the increasing demand secondary to a rising pressure.

Tracheal intubation: Severe intraoperative hypertensive episodes are particularly likely to occur at three periods: during intubation (Fig. 1), during median sternotomy and retraction of the chest wall and some time during or immediately after cardiopulmonary bypass. Induction of anesthesia by morphine sulfate[31] or the use of pancuronium bromide for muscle relaxation[32] can lead to undesirable tachycardia and an increase in arterial pressure in patients with coronary artery disease. However, a much more severe and frequent hypertension is associated with tracheal intubation. Stimulation of nerve endings in the nasopharynx by thermal probes and nasogastric tubes can lead to severe hypertension in any patient, especially in preoperatively hypertensive subjects when anesthesia is light and the stimulation prolonged. The increase in blood pressure is not usually prevented by previous antihypertensive therapy. Similar increases in pressure can also be seen on extubation.[33] These hypertensive crises can produce acute left ventricular dysfunction[22] and affect the outcome of cardiac surgery. Several protocols have been designated to minimize them. They include increasing the level of anesthesia and use of local anesthetic sprays, intravenous vasodilators, beta blocking agents and even stellate block.[34]

Sternotomy: During median sternotomy, acute hypertension was found to develop rather frequently in 47 percent in one series of 40 patients reported on by Chaptal et al.[17] and in 41 percent of 69 hypertensive episodes described by Roberts et al.[2] The increase in arterial pressure was usually associated with tachycardia, ST-T wave changes and, occasionally, multifocal ventricular premature complexes.[17] This initial elevation in pressure was associated with a later postoperative episode in 54 percent of one series.[2] The mechanisms of this hypertension have not yet been defined precisely although the clinical findings suggest sympathetic stimulation, possibly reflex in origin. The hypertensive response to sternotomy in human subjects contrasts sharply with the marked reduction in blood pressure seen on opening the chest wall in spontaneously hypertensive rats,[35] although not in rats with renal hypertension.[36] These differences in response, apparently to the same stimulus, underline the difficulty in extrapolating results from one cardiovascular setting to another.

Cardiopulmonary bypass: On initiation of cardiopulmonary bypass, mean arterial pressure usually decreases by as much as 45 percent but it begins to rise toward prebypass levels within a few minutes.[37] The reduction and subsequent increase in arterial pressure are not related to changes in cardiac output because these develop while the aorta is cross-clamped and the heart excluded from the circulation. Also, the changes in mean arterial pressure do not reflect the changes that occur in the pump output; the rise in arterial pressure is therefore mainly related to variations in peripheral vascular resistance. The cause and mechanisms of these variations have not been fully elucidated. Factors mentioned include dilating effects of priming solutions, histamine release, increase in antidiuretic hormone and alterations in circulating catecholamines.[37-39] Concerning the latter, in most reports the data have been analyzed in unifactorial terms rather than as part of a complex of interacting mechanisms.[40] In a situation entailing cross-clamping and manipulation of the aorta, activation of reflex pressor mechanisms[41] could be postulated. Less speculative are changes in circulating angiotensin II levels consequent to cardiopulmonary bypass.[4,42]

Taylor et al.[43] have shown that plasma angiotensin II levels were markedly higher during nonpulsatile bypass and that this increase could be attenuated by using pulsatile flow. Alterations in peripheral vascular resistance were said to correlate closely with changes in plasma angiotensin II; further, arterial pressure and vascular resistance decreased significantly after infusions of captopril.[43] The evidence appears quite impressive but it was derived only from observations or experiments in which mean arterial pressure was not increased.[42,43] The extension of these conclusions to hypertension was only inferential; despite the high levels of plasma angiotensin II reported, no actual hypertensive episode was described. That nonpulsatile flow can activate the renin-angiotensin system and increased angiotensin II can lead to marked vasoconstriction appear plausible; their casual relation to intraoperative hypertension has not yet been directly demonstrated.

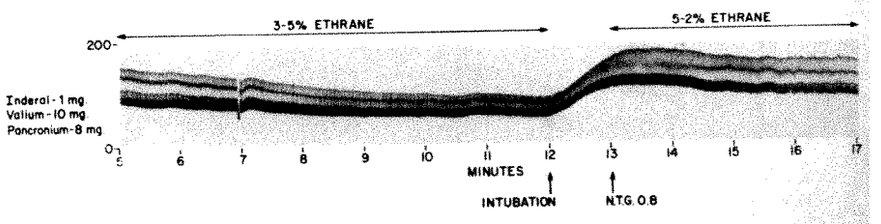

FIGURE 1. Hypertensive response to endotracheal intubation. N.T.G. = nitroglycerin.

Hypertensive episodes during cardiopulmonary bypass have not been infrequent in our experience; Roberts et al.[2] did not mention any in their series of 100 consecutive operations. When these episodes occurred the increase in pressure in our patients did not respond either to deepening the level of anesthesia or to reducing pump flow, but it was controlled by vasodilators. This increase in blood pressure did not correlate with the subsequent development of hypertension in the postoperative period.

Hypertension After Cardiac Surgery

Paroxysmal hypertension in the immediate postoperative period is a frequent and potentially dangerous condition. Many precipitating factors could be implicated: arousal from anesthesia, tracheal and nasopharyngeal manipulations, pain, hypothermia, shivering, poor ventilation and the use of pressor agents as well as the diminishing effects of antihypertensive medications. In addition, postoperative coronary insufficiency or myocardial infarction might increase blood pressure; signs of cardioadrenergic stimulation were particularly marked after coronary bypass in those patients who sustained a postoperative infarction.[20] Hypervolemia is often cited as a possible cause of postoperative hypertension. However, the relation of fluid overload to increased arterial pressure is more complex than the relation between container and content.[44] Compensatory neural mechanisms can adequately buffer sizable variations blood volume[45]; only in the functional absence of such reflexes or of renal excretory function will arterial pressure correlate directly with hypervolemia.[44,46] However, marked sympathetic reaction to hypovolemia could be an unrecognized cause of serious hypertension and impaired tissue perfusion.[47]

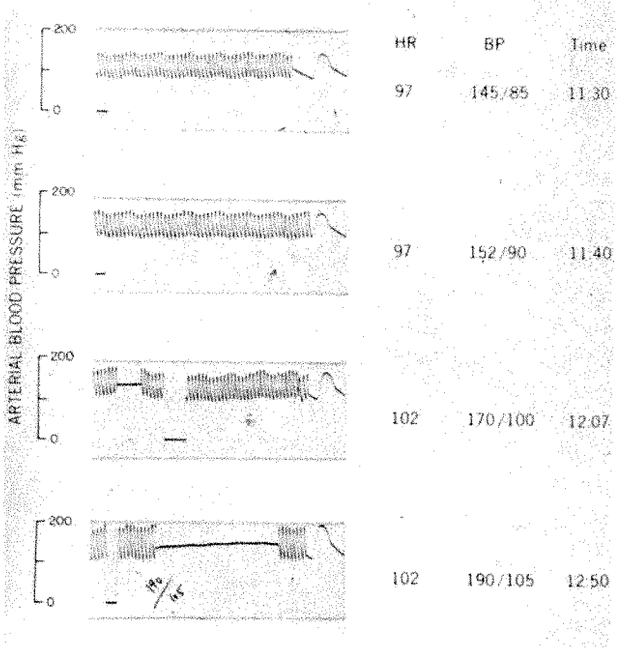

FIGURE 2. Hypertension after coronary bypass surgery. BP = blood pressure; HR = heart rate.

Early Types of Postoperative Hypertension

Postcoronary Bypass Hypertension

Since its original description in 1973,[1] this type of hypertension has been recognized as possibly the most common complication of coronary bypass surgery, occurring in 30 to 50 percent of patients.[2–4] A similar condition has also been seen after cardiac valve replacement, but the incidence rate is much smaller (8 to 10 percent).[1,10] The difference might be related to the brittleness and instability of blood pressure control in patients with coronary artery disease. Of particular importance are the reduced baroreceptor sensitivity[12] and frequent hypovolemia[48] in such patients.

The frequency of the condition and its serious implications[1–3,5] have stimulated a large number of studies; these have outlined a clinical syndrome with typical hemodynamic characteristics.[1,49] Generally agreed on are the early incidence of this hypertension in the first few hours postoperatively,[1–3] its paroxysmal course[1–3,12] and its association with mild tachycardia, increased peripheral resistance and an elevated mean rate of left ventricular ejection.[49] It has been reported as frequently among hypertensive patients as among previously normotensive subjects.[1–3]

Clinical description: The increase in arterial pressure occurs usually during the first 4 hours after operation both in patients already awake and in those still anesthetized. The blood pressure increases gradually but steadily (Fig. 2) despite adequate sedation and well controlled ventilation.[1,5] On clinical examination, we found no evidence of pallor, cyanosis or sweating, although the pressure may have occasionally exceeded preoperative levels by 60/35 mm Hg. This increase was not associated with any significant clinical sign except increased oozing and blood loss from the chest tube.[5] Despite the increase in pressure, there was no slowing of pulse rate; on the contrary, it tended to be slightly more rapid[12] with only occasional premature ventricular complexes[1]; ventricular fibrillation was reported in two patients.[17] Central venous and left atrial pressures usually remained within normal limits.[12,29]

A search for predisposing factors by several investigators did not produce any consistent results; findings were also mostly negative in our experience.[1,12] Most authors agree that the type of anesthetic agent, the duration of cardiopulmonary bypass and the distribution of coronary arterial lesions did not significantly influence the incidence of postoperative hypertension. Our impression was that this hypertension occurred more frequently among patients with well preserved myocardial function. This impression was strengthened by our experience with early systemic hypertension after cardiac valve replacement.[10] Hypertension appeared to develop somewhat more frequently after aortic valve replacement than after mitral valve replacement (12.1 versus 5.9 percent); none of the 18 patients who had double valve replacement had postoperative hypertension. This difference in incidence was attributed to

the difference in myocardial status among these groups.

Pathophysiology: The increase in blood pressure after coronary bypass surgery was related in all published reports[2,12,49,50] to an increase in total peripheral resistance. This conclusion was not based only on group averages; in our study the hemodynamic evolution after coronary surgery was described using each patient as his own control.[49] The change in hemodynamic pattern as pressure increased was the same in all patients, with no significant change in either cardiac output or central venous or left atrial pressure. These findings helped us to discount hypervolemia as a cause for this hypertension.[12] Two paradoxical findings were associated with the increase in pressure: (1) lack of slowing of heart rate, and (2) further elevation of the mean rate of left ventricular ejection. This hemodynamic pattern suggested an increased sympathetic drive that, in turn, helped to explain why cardiac output was not reduced despite the rapid increase in blood pressure.

Neural factors: The hypothesis of sympathetic stimulation was further supported by reports of statistically significant correlations between the increase in mean arterial pressure and elevations in plasma catecholamine levels.[2,12] However, these correlations were not very close, suggesting either the interplay of other factors or a lack of sufficient sensitivity of circulating catecholamines as an index of sympathetic activity.

We postulated as early as 1973 that the sympathetic overdrive was possibly related to activation of pressor reflexes from the heart, great vessels or coronary arteries. In favor of a reflex mechanism was the paroxysmal nature of the hypertension, its temporal relation to manipulation of the heart and its vessels and the absence of other obvious hemodynamic factors. The importance of pressor reflexes originating from the heart and great vessels has repeatedly been demonstrated[13,19,41,51–53]; Malliani and Brown[51] showed that depressor reflexes originating from the coronary arteries were mediated by vagal afferents in contrast to pressor reflexes that coursed through sympathetic afferents. A hypertensive chemoflex from the heart was related by James et al.[13] to a small serotonin-sensitive chemoreceptor in an area in which blood supply was derived from a special small branch of the left main coronary artery. This reflex is mediated by vagal afferents and its existence has not yet been proved in man.[13] Malliani et al.[52] reported that stretch of the thoracic aorta in cats led to reflex increases (mediated by sympathetic afferents) of arterial pressure and heart rate.

Our previous experience with stellate stimulation,[54] as well as the lack of any obvious predilection of postcoronary bypass hypertension for operations on any single coronary bed, suggested that of the various possible pressor reflexes, the more important in this context were those that involved sympathetic afferent fibers. We therefore elected to test the effect of unilateral stellate ganglion block in patients with hypertension after coronary bypass surgery. Both in our initial series of 27 patients[14] and in a subsequent larger group,[12] an effective unilateral block resulted in rapid and definitive normalization of arterial pressure in the vast majority of cases. The reduction in blood pressure was rapid, smooth and related to a decrease in systemic resistance with no evidence of diminished cardiac performance (Fig. 3).[14] These results were interpreted to indicate that the blood pressure response was probably due to interruption of afferent fibers coursing through or relaying in either stellate ganglion. If the blockade had acted mainly by interfering with efferent cardiac sympathetic drive, one would have expected a depression of cardiac output. This is what happens with acute beta adrenergic blockade; in such instances, cardiac output decreases but total peripheral resistance increases and blood pressure is left unchanged.[55] This pattern is obviously quite different from the immediate reduction in both arterial pressure and peripheral resistance produced by the unilateral stellate block. This widespread hemodynamic effect of a unilateral block suggests the interruption of a pressor reflex.

The success of stellate block does not mean that all cases of hypertension after coronary bypass surgery are due to pressor reflexes from sympathetic afferent fibers. Other causes of hypertension after cardiac surgery are known (Table I); even among those cases with no obvious cause, some hypertension might conceivably be due to activation of the hypertensive chemoflex.[13] A possible role for an activated renin-angiotensin system in some cases,[2] even if confirmed, does not necessarily contradict a "cardiac" origin for this hypertension because sympathetic stimulation is a potent cause of renin release.

Renin-angiotensin system: Reports by Roberts et al.[2] and other investigators[56–58] emphasized the pathogenetic importance of increased plasma renin activity in postcoronary bypass hypertension. Although this renin-angiotensin system can be activated during nonpulsatile cardiopulmonary bypass,[4,42,43] a definite relation of increased angiotensin II to postoperative

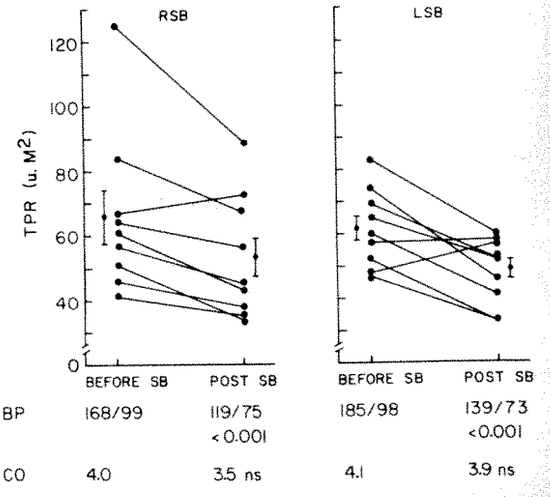

FIGURE 3. Effect of unilateral stellate block (SB) on hypertension after coronary bypass surgery. BP = blood pressure; CO = cardiac output; LSB = left stellate block; RSB = right stellate block; POST = after; TPR = total peripheral resistance.

ypertension has not, in our opinion, been demonstrated. Further, neither in our experience nor in that f others was it possible to document a particularly elvated plasma renin activity in patients in whom hyertension later developed after coronary bypass surery. No correlation was found during the postoperative eriod between changes in blood pressure and change ı plasma renin activity.[12] Converting enzyme inhibitors 'ere effective in control of hypertension after bypass ırgery,[59] but these results can hardly be considered nequivocal evidence of an angiotensinogenic causation. 'he very mechanisms by which these inhibitors de-'ease arterial pressure are themselves debated.[60]

arly Hypertension After Resection of ortic Coarctation

Hypertension after resection of coarctation of aorta as described by Sealy[61] in 1957. The increase in blood ressure occurs either early, immediately after surgery ype I), or 24 to 36 hours postoperatively (type II) 'intermediate postoperative hypertension"). The arly hypertension" was reported in more than 17 ercent of patients[61]; it lasts about 8 to 12 hours and sponds adequately to vasodilator therapy. In our exerience, its clinical characteristics are similar to those postmyocardial revascularization hypertension. The emodynamics of this type of hypertension were not udied because attention was mostly directed to the ore serious "hypertension type II."

Intermediate Hypertension

Hypertension after resection of aortic coarctaon: This type of hypertension (Sealy type II), which eveloped in 10 to 12 percent of patients, begins 36 to 3 hours after surgery; it is not related to the "early Sealy type I) hypertension" but its incidence and se-rity are related to both the tightness of the coarctation ıd the age of the patient.[61,62] The rise in pressure is ost pronounced in the diastolic levels and is usually companied by significant tachycardia; it is often mplicated by abdominal pain and signs and symms of an acute abdomen due to mesenteric endartitis.[62] The increase in pressure has been related to creased sympathetic activity consequent to reduction baroreceptor inhibition of vasomotor centers. After ccessful resection of the coarcted segment, the arterial essure decreases in the upper part of the body leading inactivation of the baroreceptors that had been acstomed to higher pressure levels. The release of mpathetic activity from tonic baroreceptor inhibition sults in a "vasoconstrictor storm" [63] with marked elation of blood pressure and heart rate. The mesenteric ssels that were used to the lower level of pressure evailing below the level of the coarctation are now ddenly exposed to severe hypertension, precipitating darteritis and vascular necrosis with consequent instinal ischemia and infarction. Clinical awareness of is syndrome and routine early prophylactic antihyrtensive agents have minimized the incidence of this mplication.

Late Hypertension

Aortic valve replacement by homograft: Layton et al.[16] reported in 1973 a type of late postoperative hypertension after aortic valve replacement by homograft. In their experience, this hypertension occurred in up to 50 percent of patients; in some cases the blood pressure began to increase early after surgery, but the incidence of hypertension gradually increased to involve more than half of their 116 patients 5 years after valve replacement. This incidence was much greater than that expected from general statistical considerations for this particular population. The development of hypertension was not related to preoperative blood pressure levels; however, it was more frequent in male than in female patients and in those who underwent surgery for aortic regurgitation than in those who had aortic stenosis. Neither the cause nor mechanisms of the increase in blood pressure were clear; what was significant was the high rate (40 percent) of homograft valve failure in patients with uncontrolled hypertension as compared with the 11 percent of failure in those who remained normotensive or whose blood pressure was adequately controlled.

Treatment

Whatever the causes and timing of hypertension, it is a serious complication for patients recovering from open heart surgery. The increase in pressure and in total peripheral resistance increases cardiac work and myocardial oxygen consumption. Previous studies[50,64] demonstrated that the endocardial viability ratio, as well as the ratio of diastolic to systolic pressure time indexes, was lower in patients who had postoperative hypertension than in those who remained normotensive. The decrease in these indexes means an increased susceptibility to subendocardial ischemia, which can be further aggravated by the anemia due to the hemodilution that is often used in heart surgery.[65] Hypertension also increases the risk of cerebrovascular accidents. The incidence and amount of postoperative bleeding in a previously heparinized patient are much greater during hypertension. It is evident, therefore, that every effort should be made to prevent, control and treat hypertension promptly and adequately during various stages of heart surgery.

Adequate treatment depends on correct diagnosis. Wide variations can and do occur in blood volume, total peripheral resistance, pulmonary vascular resistance, myocardial perfusion and contractility and heart rate, both during and after cardiac surgery. Hence, a correct diagnosis must be based on adequate monitoring and thoughtful interpretation of various indexes. These entail close follow-up (using properly calibrated equipment) of both pulmonary and systemic arterial pressures, as well as the filling pressure in the right heart chamber and, if possible, also in the left chambers. Determination of cardiac output and estimate of fluid balance are important in certain conditions. A rational choice of therapy is made easier by defining the mechanisms underlying the rise of arterial pressure at dif-

erent stages of surgery or of the postoperative pe-iod.

General Measures

Attention to details, thoughtful preparation of the patient and general measures to avoid pain and vasoconstriction are more important in preventing hypertension or in treating it than hasty use of antihypertensive agents. Prophylaxis begins long before surgery. In our opinion, antihypertensive therapy including beta adrenergic blocking agents should be continued until the time of surgery. Hypotension, whether or not it is related to antihypertensive therapy, can be averted by good monitoring, and we believe that in proper circumstances its risks are far less than the deleterious effects of uncontrolled hypertension. Although each case should be handled on its own merits it has been our impression that maintaining antihypertensive therapy is preferable. However, cessation of administration of diuretic drugs for 1 or 2 days may help avoid the risk of dehydration in patients who may have marginal renal function.

Hypertension due to pain and anxiety is minimized by adequate premedication with a strong analgesic agent (morphine sulfate) and an amnesic agent (scopolamine). During the postoperative period all patients should receive, in doses adjusted according to their hemodynamic status, sufficient analgesic and sedative agents every 2 hours for the first 48 hours and when required thereafter to ensure that they remain free of pain.[65]

Hypothermia and vasoconstriction do occur in both the operating room and the intensive care unit. When the the patient is rewarmed after hypothermic perfusion, body temperature may drift down again; hypothermia may also occur from exposure of the patient with open chest to the relatively low operating room temperature. Both nasopharyngeal and rectal temperatures must be closely monitored and all administered fluids warmed to 37° C. Warming blankets are used when needed to avoid the vasoconstriction provoked by cold.

Antihypertensive Agents

Peripheral vasodilators: Short-acting peripheral vasodilators that do not overstimulate the heart are the drugs of choice for treatment of hypertension during and after cardiac surgery. These vasodilators have a rapid onset of action and their dose can usually be titrated to achieve the desirable level of blood pressure. However, all vasodilators are not equivalent in their spectrum of action; those like diazoxide or hydralazine, which have little effect on veins may produce undue stimulation of the heart.[66] More appropriate to the conditions of cardiac surgery are vasodilators like sodium nitroprusside, which dilate veins as well as resistance vessels.[66]

Sodium nitroprusside: This vasodilator is the most consistently effective drug for management of hypertensive crises.[67] In our opinion, it remains the drug of choice for hypertension associated with acute coronary insufficiency and left ventricular impairment.[68–71] Left ventricular stroke work and filling pressure are decreased and left ventricular performance is enhanced.[69–71] Cardiac output could be increased, particularly when the left ventricular filling pressure is initially high and left ventricular function impaired; when left ventricular filling pressure is normal or low, cardiac output might be decreased to a variable extent. Similarly, heart rate is increased in subjects without heart disease but it is not significantly altered in those with cardiac decompensation.[69]

Nitroglycerin: For the last 10 years we have used different preparations of nitroglycerin perioperatively in open heart surgery.[72] It is a peripheral vasodilator for both resistance and capacitance vessels[73] with beneficial effects on the coronary circulation; in cardiac surgery it has proved useful as a short-acting hypotensive agent.

We have utilized nitroglycerin ointment (2 percent) in our routine premedication for all patients undergoing open heart surgery. Its effect begins 20 to 30 minutes after application and may last up to 3 hours[74]; patients are advised not to stand up after its administration, to prevent orthostatic hypotension. It is used to reduce preoperative angina pectoris and consequent reflex increases in blood pressure; moreover, its routine use may decrease the incidence and degree of the hypertension that complicates endotracheal intubation. For actual angina at any stage before induction, *sublingual nitroglycerin* is given as needed. It is also given in the postoperative period every 2 hours during the first 48 hours to all patients with coronary artery disease to minimize the incidence of the pain and hypertension that can result from coronary insufficiency.[18] However, as a more direct hypotensive agent, we have used *intravenous nitroglycerin* as an alternative to sodium nitroprusside when hypertension occurs during cardiac surgery. Because of its venodilating effect and its effect on the pulmonary circulation we believe that it is the drug of choice for the hypertension associated with right ventricular dysfunction or with increased pulmonary vascular resistance.

Diazoxide: Diazoxide and other predominantly arteriolar vasodilators greatly increase cardiac output and may result in hyperkinetic pulmonary hypertension, particularly in patients with diminished left ventricular function or compliance.[66] Hence, these vasodilators may be undesirable in patients with long-standing hypertension, after open heart surgery and in cases of fixed obstruction to pulmonary venous flow (mitral stenosis).[75]

Beta adrenergic blocking agents: In patients with marked tachycardia, particularly in association with ischemic S-T segment changes, intravenous propranolol can be used in the early stages of surgery. In this situation, slowing of the heart rate can be associated with some reduction in arterial pressure, especially the systolic level. However, because of its depressing effect on myocardial contractility and its relatively delayed hypotensive action,[76] propranolol is not recommended for postoperative hypertension.

Specific Measures

Whenever the exact mechanism or cause of the hypertensive episode is known, the best treatment is specific correction of the abnormality, if possible. Every effort must be spent toward ensuring that the increase in pressure is not related to a correctable cause such as poor oxygenation, asynchrony with the ventilator or fluid overload. In all such cases, correction of the cause will lead to cure of the hypertension. In other instances, the best treatment is anticipation of some particularly frequent types of hypertension. Finally, some specific measures have been recently developed to deal with particular forms of hypertension.

Hypertension related to tracheal and nasopharyngeal manipulation: The pressor response to tracheal intubation is particularly exaggerated in preoperatively hypertensive patients[77] and whenever the stimuation is prolonged.[78] Maintenance of antihypertensive therapy might help reduce the severity of the increase in pressure. Strengthening the level of anesthesia with use of a strong inhalational agent such as halothane might minimize the pressor response in some patients; however, short-acting antihypertensive drugs administered seconds before intubation have also been used successfully including alpha adrenergic blocking agents (phentolamine)[79] and vasodilators (intravenous bolus injection of sodium nitroprusside, 1 to 3 μg/kg body weight).[80] However, too rapid a decrease in blood pressure before intubation may have a deleterious effect, especially in hypertensive or atherosclerotic patients.[77] However, in our experience ensuring the smoothness and rapidity of intubation is the most successful means of preventing or reducing an increase in blood pressure.

Unilateral stellate block: Unilateral stellate ganglion blockade was effective in our experience[12] for rapid normalization of the elevated blood pressure in a large number of patients with hypertension after myocardial revascularization (Fig. 3) as well as in those with a hypertensive episode immediately after heart valve replacement. We have even found stellate block to be effective after large doses of peripheral vasodilators failed to control adequately the paroxysmal increase in pressure. However, unless this blockade is performed with great care by physicians trained in its use, the incidence of its success rate can be quite low and, more important, can be complicated by pneumothorax, hemothorax or nerve injury.[81] Bilateral stellate block is dangerous because of the possibility of undue cardiac depression.

Angiotensin II antagonists and converting enzyme inhibitors: These drugs, which interfere at different levels with the renin-angiotensin cascade, have been shown to reduce blood pressure very effectively when circulating angiotensin II levels are high. Most agents reduce peripheral resistance without significantly changing cardiac index, an effect similar to that produced by vasodilators acting at both the arteriolar and venular levels.[59,82] No significant tachycardia has been noted with their use; the heart rate remained remarkably stable despite marked reduction of blood pressure in hypertensive patients.[82–84] Because of these favorable hemodynamic characteristics these drugs may be particularly useful in hypertensive patients with heart disease, and have been tried successfully in the treatment of hypertension after myocardial revascularization.[59] However, both classes of drugs are still investigational; currently, only the angiotensin antagonists (saralasin) and teprotide can be given intravenously.

election of Angina-Free Patients With Severe eft Ventricular Dysfunction for Myocardial Revascularization

ARY W. AKINS, MD
ERALD M. POHOST, MD, FACC*
OMAN W. DESANCTIS, MD, FACC
ETER C. BLOCK, MD, FACC

oston, Massachusetts

Stress thallium-201 myocardial imaging was used in two angina-free patients with severe congestive heart failure to identify clinically silent areas of ischemic myocardium and to distinguish between scar and reversibly ischemic myocardium as a cause for akinesia of left ventricular wall segments. Subsequent myocardial revascularization in these patients led to considerable improvement in their clinical state and findings in postoperative nuclear scans. Thus, stress myocardial imaging may be useful in selecting patients with severe left ventricular failure but no angina pectoris for myocardial revascularization.

Congestive heart failure secondary to left ventricular dysfunction from diffuse coronary artery disease is generally considered to be a relative contraindication to myocardial revascularization, particularly when it occurs in the absence of angina pectoris. However, patients are occasionally encountered with congestive heart failure due to known coronary artery disease who have no angina, but in whom there may be reason to suspect that clinically unrecognized ischemia may be contributing importantly to left ventricular dysfunction. Left ventricular angiography alone does not distinguish scarred myocardium from viable myocardium that is akinetic because of severe ischemia. Stress myocardial imaging with thallium-201 can differentiate viable myocardium from scar and therefore ought to be useful in selecting for revascularization patients with poor left ventricular function.

Two patients with severe coronary artery disease are described whose only clinical manifestation was congestive heart failure. Both patients had had multiple myocardial infarctions and had been considered for coronary revascularization elsewhere. Surgery was not advised on the basis of poor ventricular function and lack of angina pectoris. Both patients underwent thallium-201 exercise imaging of the myocardium, which revealed extensive areas of reversibly ischemic akinetic myocardium. On the basis of these findings myocardial revascularization was performed and resulted in considerable improvement in the condition of both patients.

Case Reports

Case 1

A 68 year old retired government worker presented to the Massachusetts General Hospital for evaluation of increasing congestive heart failure. The pa-

rom the Cardiovascular Surgical and Cardiac Units of the Departments of Surgery and Medicine, Massachusetts General Hospital, Fruit Street, Boston, Massachusetts. Manuscript received February 25, 1980; revised manuscript received April 14, 1980, accepted April 18, 1980

*Established Investigator of the American Heart Association, Dallas, Texas.

Address for reprints: Cary W. Akins, MD, Department of Surgery, Massachusetts General Hospital, Boston, Massachusetts, 02114.

tient, who smoked 80 pack-years of cigarettes and had a 2 year history of diabetes mellitus of adult onset, had had two myocardial infarctions, one in 1966 and the second in 1977. During both infarctions he had had severe dyspnea and diaphoresis but no chest pain. In October 1978, he was admitted elsewhere for cardiac evaluation because of increasing symptoms of congestive heart failure. He was unable to walk up one flight of stairs or a quarter of a mile on flat ground without becoming severely short of breath. He denied any angina pectoris.

Angiographic findings: Cardiac catheterization before admission documented a left ventricular end-diastolic pressure of 36 mm Hg, which increased to 41 mm Hg after angiography, a pulmonary arterial pressure of 48/27 mm Hg and a cardiac index of 1.6 liters/min per m^2. Coronary cineangiography demonstrated total occlusion of the right coronary artery and high grade obstructive lesions of the left circumflex coronary artery and of the left anterior descending coronary artery and its first diagonal branch. Left ventriculography demonstrated anteroapical akinesia and otherwise generalized severe hypokinesia; left ventricular ejection fraction was estimated as 15 percent. Because of the patient's severe left ventricular dysfunction and lack of angina pectoris, he was not considered a suitable candidate for coronary bypass surgery.

Cardiac examination: He was admitted for the first time to the Massachusetts General Hospital in January 1979 because of symptoms of increasing left-sided congestive heart failure. Physical examination revealed a man in moderate respiratory distress. Blood pressure was 160/90 mm Hg, the pulse rate was 120/min, and respirations were 28/min and somewhat labored. Jugular venous pressure was increased to the angle of the jaw at 90°, but there was no peripheral edema. There were rales at both lung bases. Cardiac examination showed a prominent left ventricular impulse palpable in the sixth intercostal space in the anterior axillary line. There was a very prominent summation gallop and a grade 2/6 apical systolic murmur. There were no pulses below the femoral arteries bilaterally. The chest roentgenogram showed cardiac enlargement with interstitial pulmonary edema. The electrocardiogram revealed evidence of inferior and anteroseptal scars and left ventricular hypertrophy.

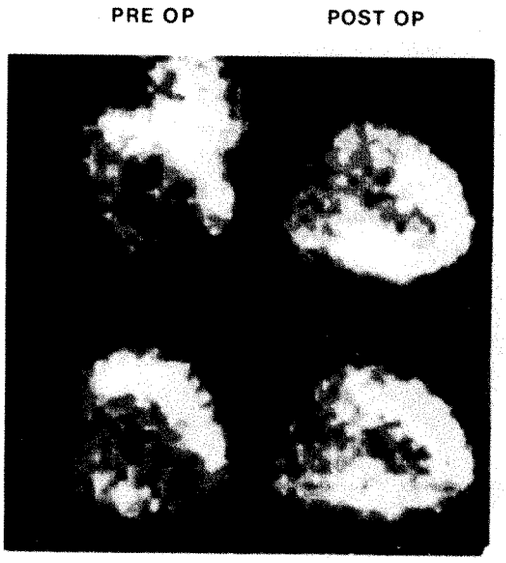

FIGURE 1. Case 1. Initial (INIT.) and delayed exercise thallium-201 imaging studies in the anterior (ANT) projection both before (PRE OP) and after (POST OP) coronary bypass graft surgery. The initial preoperative image shows a large defect involving the inferior and apical segments. In the delayed study the inferior wall demonstrates substantial thallium-201 fill in, and the apical defect persists. These findings suggest that despite the akinesia manifested on left ventricular cineangiography and gated blood pool scanning, the inferior wall is viable. In addition, the initial preoperative scan demonstrates increased lung activity that disappears in the delayed scan, suggesting that transient left ventricular failure was present at the time of the thallium injection. In the postoperative study, thallium-201 activity distribution appears normal, and lung activity is no longer evident.

Radionuclear imaging: After improvement in the patient's clinical status after diuresis and weight loss of 4.5 kg, a gated cardiac blood pool scan demonstrated a severely depressed left ventricular ejection fraction of 15 percent. The right ventricle contracted well. An exercise thallium stress test revealed areas of septal and inferoapical reversible ischemia (Fig. 1).

Cardiac surgery: In March 1979, saphenous vein aortocoronary bypass grafts were constructed to the left anterior descending, diagonal, circumflex marginal and posterior descending coronary arteries. At operation, the left ventricle was found to be markedly enlarged but without localized evidence of transmural myocardial infarction. The patient's pulmonary capillary wedge pressure before the institution of cardiopulmonary bypass was 28 mm Hg. He was weaned from cardiopulmonary bypass with a left atrial pressure of 14 mm Hg without any medications. The following morning the patient had a blood pressure of 130/70 mm Hg, a pulse rate of 95/min, a left atrial pressure of 11 mm Hg and a cardiac index of 2.4 liters/min per m^2. The rest of the patient's postoperative course was uneventful, and he was discharged to his home on the 18th postoperative day.

Postoperative course: A second gated cardiac blood pool scan performed 7 weeks after operation revealed an ejection fraction of 27 percent. An exercise thallium scan demonstrated more homogeneous distribution of the isotope throughout the left ventricular myocardium with activity present in the septum and inferior wall in the initial as well as in the delayed study (Fig. 1). Eight months postoperatively the patient is doing well and is limited only by lower limb claudication.

Case 2

A 40 year old mechanic was referred to the Massachusetts General Hospital for evaluation of increasing shortness of breath. The patient, previously a heavy smoker, had a posterolateral myocardial infarction in August 1977. He did well until September 1978, when he had an anteroseptal myocardial infarction. His second infarction was complicated by mild congestive heart failure. Six weeks after his second infarction he had 3 nights of paroxysmal nocturnal dyspnea. Evaluation at that time revealed a new murmur of mitral insufficiency.

Previous angiographic findings: During evaluation elsewhere the patient complained of fatigue, exertional dyspnea and weight loss but denied any angina pectoris or peripheral edema. At cardiac catheterization the following pressures were measured (in mm Hg): aortic 86/62, left ventricular 85/35, pulmonary arterial 53/26 (mean 32), pulmonary capillary wedge 36 (with V waves to 50), right ventricular 57/17 and right atrial 9. The cardiac index was 1.7 liters/min per m^2. Coronary arteriography revealed a normal nondominant right coronary artery and significant stenoses of the left

nterior descending, the first large diagonal and the circumflex narginal coronary arteries. Left ventriculography revealed a large anteroapical akinetic area with otherwise generalized evere hypokinesia. There was considerable mitral regurgiation, and the ejection fraction was estimated to be 12 to 15 ercent. Because of the patient's severe left ventricular failure ithout angina pectoris, he was thought not to be a suitable andidate for surgery. Subsequently, he did poorly and had vidence of right-sided failure with ascites and peripheral dema. His diuretic dosage was increased, and he was referred o the Massachusetts General Hospital.

Cardiac findings: On admission in February 1979, he was ound to be moderately dyspneic with a blood pressure of 0/80 mm Hg and a regular pulse (rate 70/min). His heart was narkedly enlarged and there was a diffuse left ventricular mpulse. There were S_3 and S_4 gallops and a grade 3/6 systolic murmur of mitral regurgitation. The electrocardiogram on dmission revealed sinus rhythm with evidence of old inferoposterior and anterior infarctions. The admission chest oentgenogram demonstrated marked cardiomegaly with mild nterstitial edema and left atrial enlargement.

A thallium stress test revealed reversibly ischemic segments in the interventricular septum and the high anterior wall of the heart with a large scar in the inferoapical wall (Fig. 2).

Cardiac surgery: At operation in February 1979, there was massive enlargement of both the left ventricle and right-sided chambers. Saphenous vein aortocoronary bypass grafts were constructed to the diagonal, left anterior descending and circumflex marginal coronary arteries. Two akinetic scarred segments were resected, a large area of the posterior wall of the heart measuring 4 by 13 cm and an area between the left anterior descending and diagonal coronary arteries at the apex measuring 3 by 5 cm. The mitral valve was excised and replaced with a 33 Hancock porcine xenograft valve. The patient was weaned from cardiopulmonary bypass with atrial pacing, with a systolic blood pressure of 130 mm Hg and a left atrial mean pressure of 16 mm Hg after infusion of a small amount of nitroprusside and dopamine.

Postoperative course: Some right ventricular failure resolved in the early postoperative period with a steady increase in the cardiac index. By the 4th postoperative day the patient had a blood pressure of 110/70 mm Hg, a pulse rate of 100, a left atrial pressure of 14 mm Hg and a cardiac index of 2.5 liters/min per m^2 without pressor support. His subsequent postoperative course was one of steady improvement. He was discharged home on the 14th postoperative day.

A second gated cardiac blood pool scan performed 13 months after operation revealed an ejection fraction of 33 percent. A thallium exercise scan showed normal septal, anterior and high lateral wall uptake with a persistent defect in the inferoapical wall that was smaller than that seen preoperatively. Thirteen months postoperatively the patient is very active and has only mild fatigue on exertion.

Discussion

These two cases demonstrate the difficulty in selecting for myocardial revascularization those patients who have silent myocardial ischemia. In both patients the problem was accentuated by the presence of congestive heart failure and by the difficulty in assessing the role that reversible ischemia might have played in its origin.

Angina pectoris versus left ventricular heart failure as a clinical marker of ischemia: Because angina pectoris is a specific clinical marker of myocardial ischemia, angina has become almost synonymous with the clinical presentation of coronary artery disease.[1,2] However, the sensitivity of angina as a clinical marker of severe coronary artery disease is probably very low. Various studies in the past have examined the incidence of prodromal angina pectoris before myo-

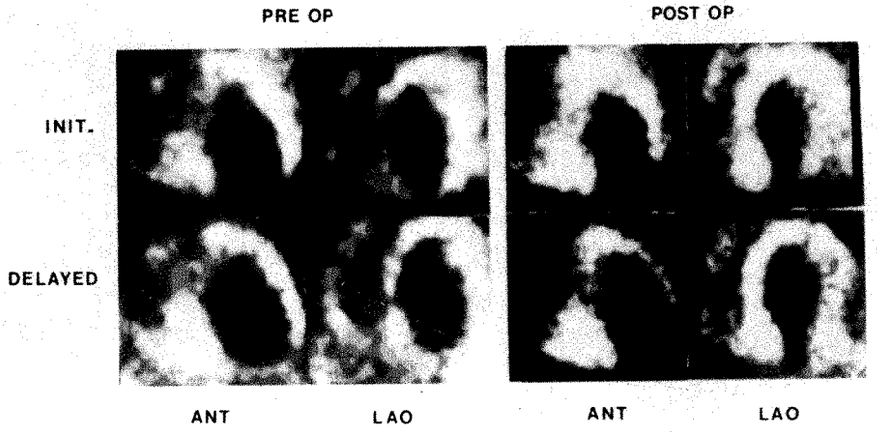

FIGURE 2. Case 2. Anterior (ANT) and 50° left anterior oblique (LAO) exercise thallium-201 myocardial imaging studies before (PRE OP) and after (POST OP) coronary bypass graft surgery. Initial (INIT.) and 2 hour delayed images are displayed with the initial scan in the **top row** and delayed images in the **bottom row.** The preoperative study demonstrates large initial defects in the inferior and apical segments in the anterior view and inferoapical and septal segments in the left anterior oblique view. All of these defects tended to be filled in, at least partially, in the delayed study. The postoperative study demonstrates only persistent defects in the inferoapical segment, which appear somewhat smaller than those in the preoperative study. The septum and high anterolateral wall appear to have improved perfusion in the postoperative study. Increased lung activity is present initally both preoperatively and postoperatively, a finding consistent with exercise-induced left ventricular failure. This lung activity can be seen in the **upper right corner** of each initial anterior image; it is less impressive in the postoperative study.

cardial infarction,[3–8] including a recent report[9] in which 48 percent of 577 patients presenting to the hospital with acute myocardial infarction had no prior history of angina pectoris. For these patients the myocardial infarction itself was the initial manifestation of clinically severe coronary artery disease. Other clinical presentations of coronary artery disease include functional mitral insufficiency, atrial and ventricular arrhythmias, congestive heart failure and atypical pain and dyspnea syndromes that have often been grouped under the term "anginal equivalents." In a broader sense it might be better to group these symptoms, as well as angina itself, under the term "ischemic equivalents of coronary artery disease."

Nevertheless, for most physicians angina pectoris remains a mandatory clinical correlate to anatomic disease as an indication for bypass surgery, and medically refractory angina pectoris is still the principal indication for myocardial revascularization. However, data[10–12] have recently appeared on surgical therapy for "asymptomic" patients (that is, patients without angina pectoris.) Our two cases support the view that it is not appropriate to exclude patients from consideration for myocardial revascularization purely on the basis of the absence of angina pectoris.[13]

Early surgical series[14,15] documented a small therapeutic benefit and a high operative mortality rate for myocardial revascularization in patients with severe left ventricular dysfunction. Most of the patients in those series had angina pectoris. More recent studies[16–18] have shown improved results in similar patients and hospital mortality rates of approximately 10 percent. Because it is difficult with left ventricular angiography to differentiate between reversible and irreversible left ventricular failure associated with ischemic heart disease, few surgeons feel comfortable in performing myocardial revascularization in patients with profound left ventricular dysfunction who do not also have significant angina pectoris.

Radionuclear myocardial imaging to detect ischemia in absence of angina: Thus, given that the absence of angina pectoris does not preclude life-threatening coronary artery disease in many patients and given the inability of left ventricular angiography to differentiate between left ventricular scar and segments that are akinetic because of ischemia, other methods have been used to try to verify the presence of myocardial ischemia and quantify its severity. The most widely applied of these methods is exercise electrocardiography. The reliability and specificity of exercise stress testing in asymptomatic patients have been reported to be quite low.[19] The addition of stress myocardial imaging with thallium-201 has enhanced the diagnostic accuracy of the electrocardiogram for the detection of coronary artery disease.[20,21] Some investigators[22,23] have reported radioactive microsphere distribution as a technique for identifying ischemic myocardium. In our patients we utilized myocardial imaging with thallium-201 both to identify myocardial ischemia that is not clinically evident and to differentiate between reversibly ischemic and irreversibly scarred myocardium.

Previous reports[20] indicate that serial imaging after a single dose of thallium-201 can differentiate between reversibly ischemic and scarred myocardium. Both ischemic and scarred myocardium will usually be observed as defects in the immediate postexercise scan. Ischemic defects fill in over time, whereas defects from scarring persist. Wall motion can be reduced secondary to reversible ischemia as well as scar. Thus, areas that demonstrate delayed thallium uptake are believed to be consistent with reversible ischemia, and when such areas correspond to bypassable coronary arterial lesions as determined from coronary cineangiography, a beneficial effect on segmental wall function from bypass surgery might be anticipated. Obviously when mechanical lesions such as mitral insufficiency, ventricular aneurysm and ventricular septal defect are combined

TABLE I
Preoperative and Postoperative Measurements of Ventricular Function

Variables of Ventricular Function	Case 1		Case 2	
	Preop	Postop	Preop	Postop
NYHA class[33]	IV	II	IV	II

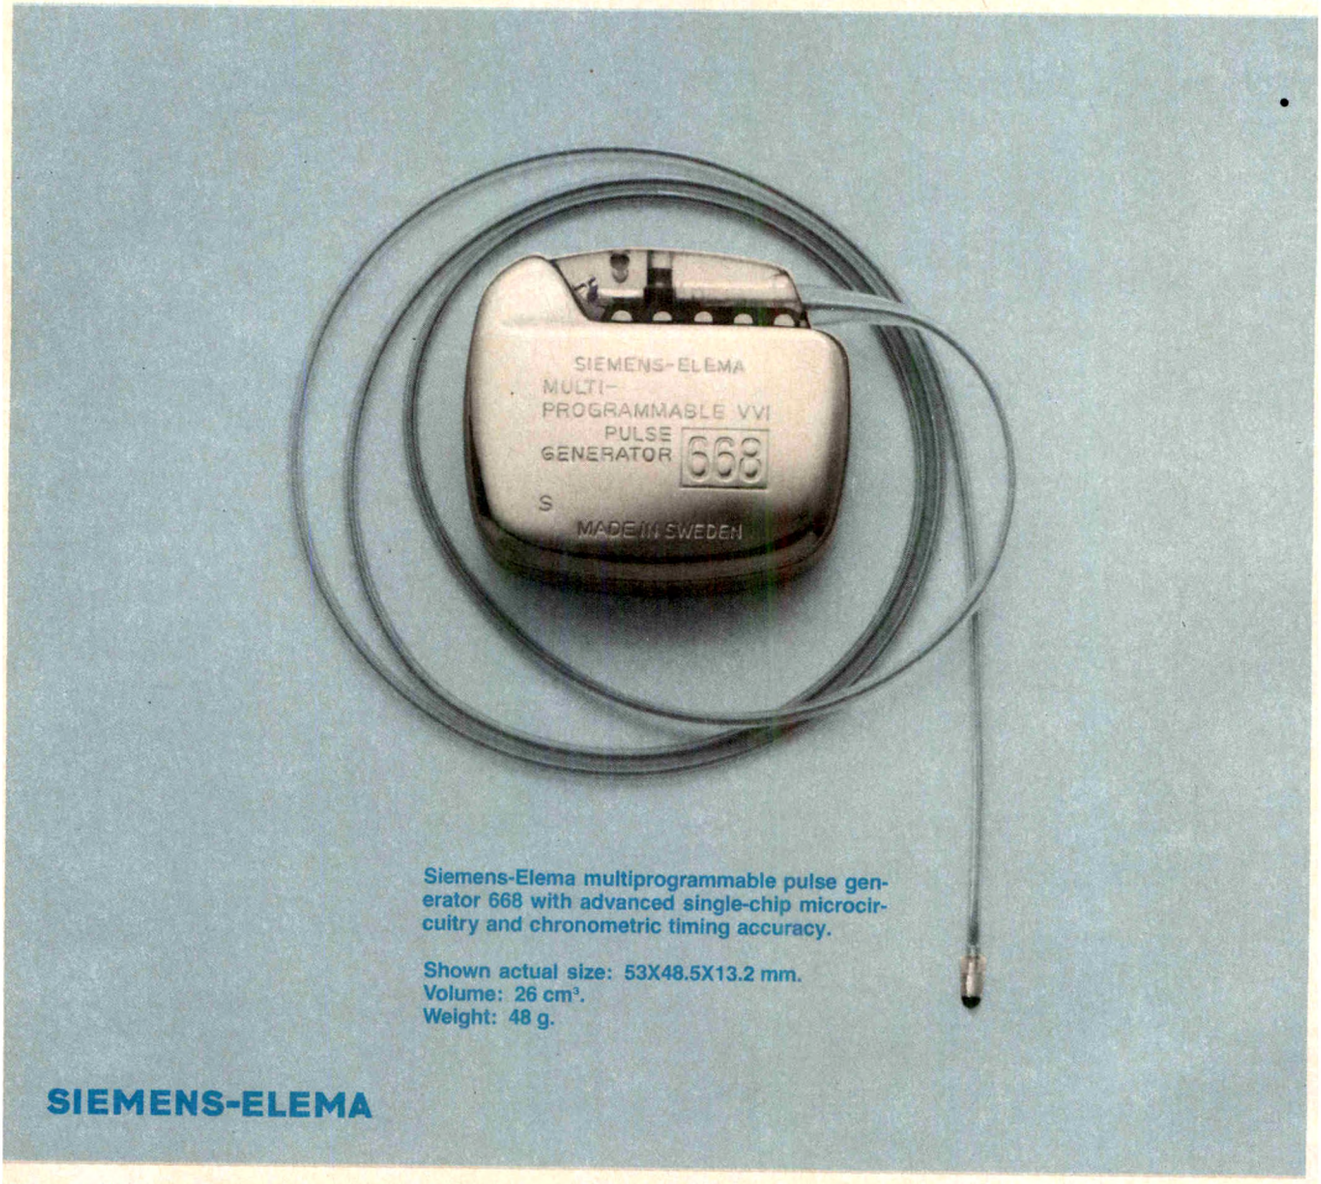
with areas of reversible ischemia and operable coronary artery disease, their simultaneous correction is likely to have an even greater potential for relieving congestive heart failure. Accordingly, the presence of left ventricular failure associated with coronary artery disease does not necessarily preclude a treatable situation. In the presence of reversible ischemia predicted on the basis of the thallium study, segmental asynergy would be anticipated to be reversible, and under these circumstances bypass surgery might be effective.

Results of surgery: The presence of two prior painless myocardial infarctions in the first of our patients made us wonder if he might have exercise-induced ischemia without pain that was contributing to his left ventricular failure. His good surgical result seems to have justified that assumption. In the second patient the postoperative improvement in left ventricular function can be explained at least in part by the correction of mitral regurgitation and removal of left ventricular scar. However, the considerable improvement in findings on postoperative thallium myocardial imaging leads us to believe that correction of silent myocardial ischemia might have played at least a partial role in his improved postoperative condition.



Multiple procedures have been used to evaluate the ability of myocardial revascularization to improve ventricular function. Various investigators[24–29] have documented hemodynamic improvements after revascularization, as well as improved response to atrial pacing,[30] changes in myocardial metabolism,[31] and improvements in myocardial perfusion or left ventricular function, or both, as measured by radionuclide scanning.[32] In addition to the marked subjective clinical improvement in both patients, there was objective evidence (Table I) of improvement in left ventricular function as shown by postoperative hemodynamic measurements, cardiothoracic ratio, ejection fraction and exercise tolerance, and improvement in myocardial perfusion as shown by myocardial imaging. This improvement was anticipated preoperatively by the presence of reversible ischemia with thallium-201 imaging.

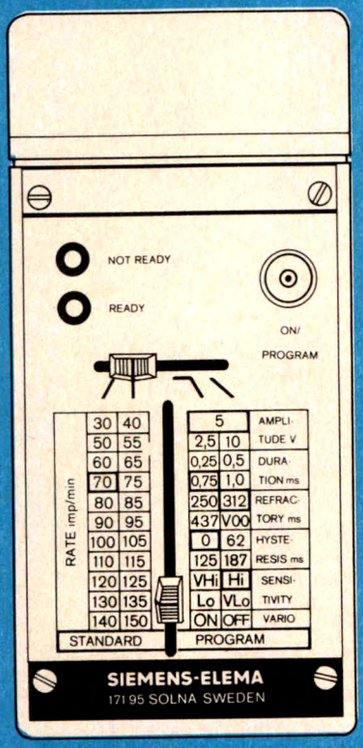
STATE OF THE ART:

Siemens-Elema multiprogrammable pulse generator 668 with advanced single-chip microcircuitry and chronometric timing accuracy.

Shown actual size: 53X48.5X13.2 mm.
Volume: 26 cm^3.
Weight: 48 g.

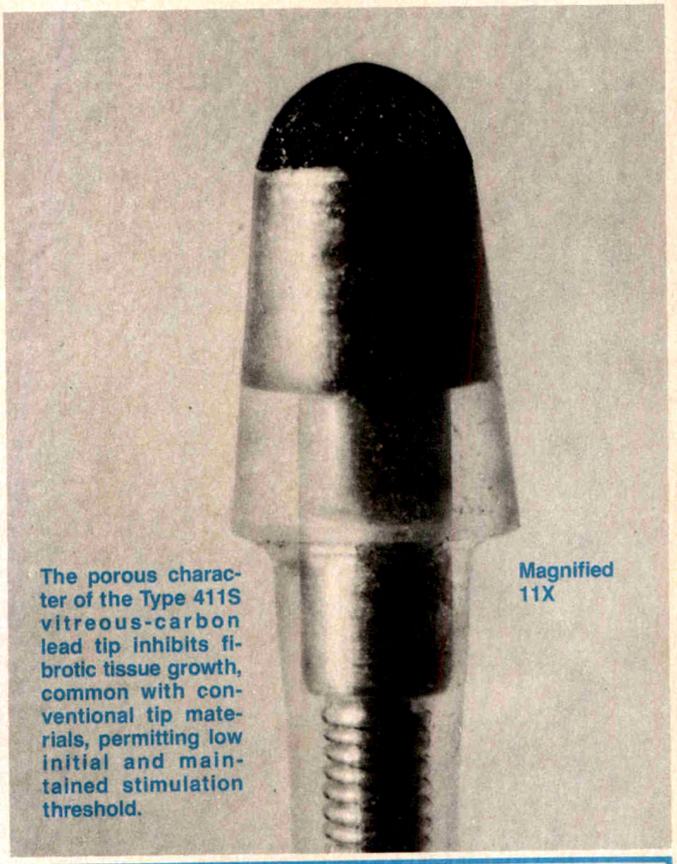
SIEMENS-ELEMA

Perhaps never before has there been a pacing system so responsive to your needs.



With six programmable parameters (including amplitude as high as 10 V) and the Vario® function, the versatile 668 generator offers more than 30,000 operating combinations.

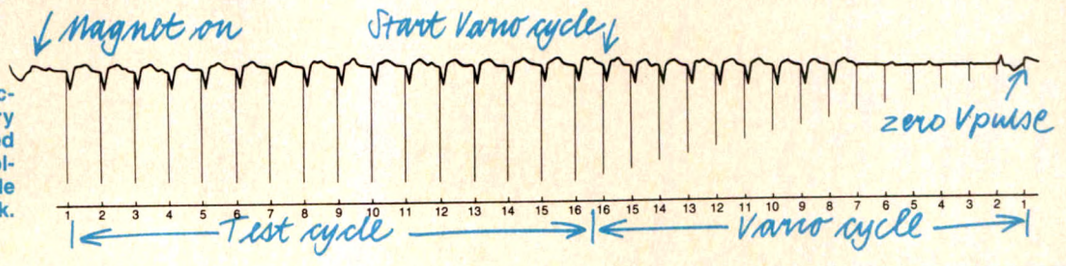
The exclusive Vario function permits easy determination of stimulation threshold—a check readily performed by support staff as part of standard routine.



The Type 411S low-threshold, vitreous-carbon lead tip promises extended generator service life and an end to complications such as exit block and sensing

THE COMPLETE MULTIPURPOSE PACING SYSTEM

THE MULTIPROGRAMMABLE PULSE GENERATOR 668.
FROM SIEMENS-ELEMA—THE PEOPLE WHO PIONEERED
THE FIRST IMPLANTABLE PACEMAKER IN 1958.



Programming unit for 668 generator features simple and straightforward operation, can also be used as pulse generator test magnet.

The porous character of the Type 411S vitreous-carbon lead tip inhibits fibrotic tissue growth, common with conventional tip materials, permitting low initial and maintained stimulation threshold.

Magnified 11X

Plot of Vario function displays battery test cycle initiated by test magnet followed by Vario cycle for threshold check.

THE TRENDSETTER™ — The top-of-the-line scanner for integrated ECG, blood pressure and pacemaker evaluation, together with comprehensive alphanumeric/graphic summaries.

VIS-U-SCAN™ — The high-speed system that puts 24 hours of ECG in your hands in three minutes flat without missing a beat.

SMART SCANNERS, SMART VALUES

There's a Del Mar Avionics ECG scanner that satisfies your most exacting requirements — in the hospital or in your office. And a worldwide network of servi centers assures fast, professional response when you need it, where you need it.

An outstanding Education and Training staff rounds out our commitment to excellence. Training courses extend the skills and knowledge of your staff in the apı cation of ECG principles to Holter System data analysis.

Our full line of smart scanners coupled with the extra services only a leader can provide, makes your investment in a Del Mar Avionics system a smart move. C your local representative today.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Yorke Medical Books AJC 10/80
666 Fifth Avenue, New York, N.Y. 10103

Please send me a copy of EXERCISE in Cardiovascular Health and Disease for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($33.00 plus shipping cost). Otherwise, the book will be returned for full refund or credit.

☐ Full payment enclosed, publisher pays shipping.
☐ Please bill me, plus cost of shipping.
☐ Charge my credit card: ☐ MasterCard ☐ Visa.

against angina

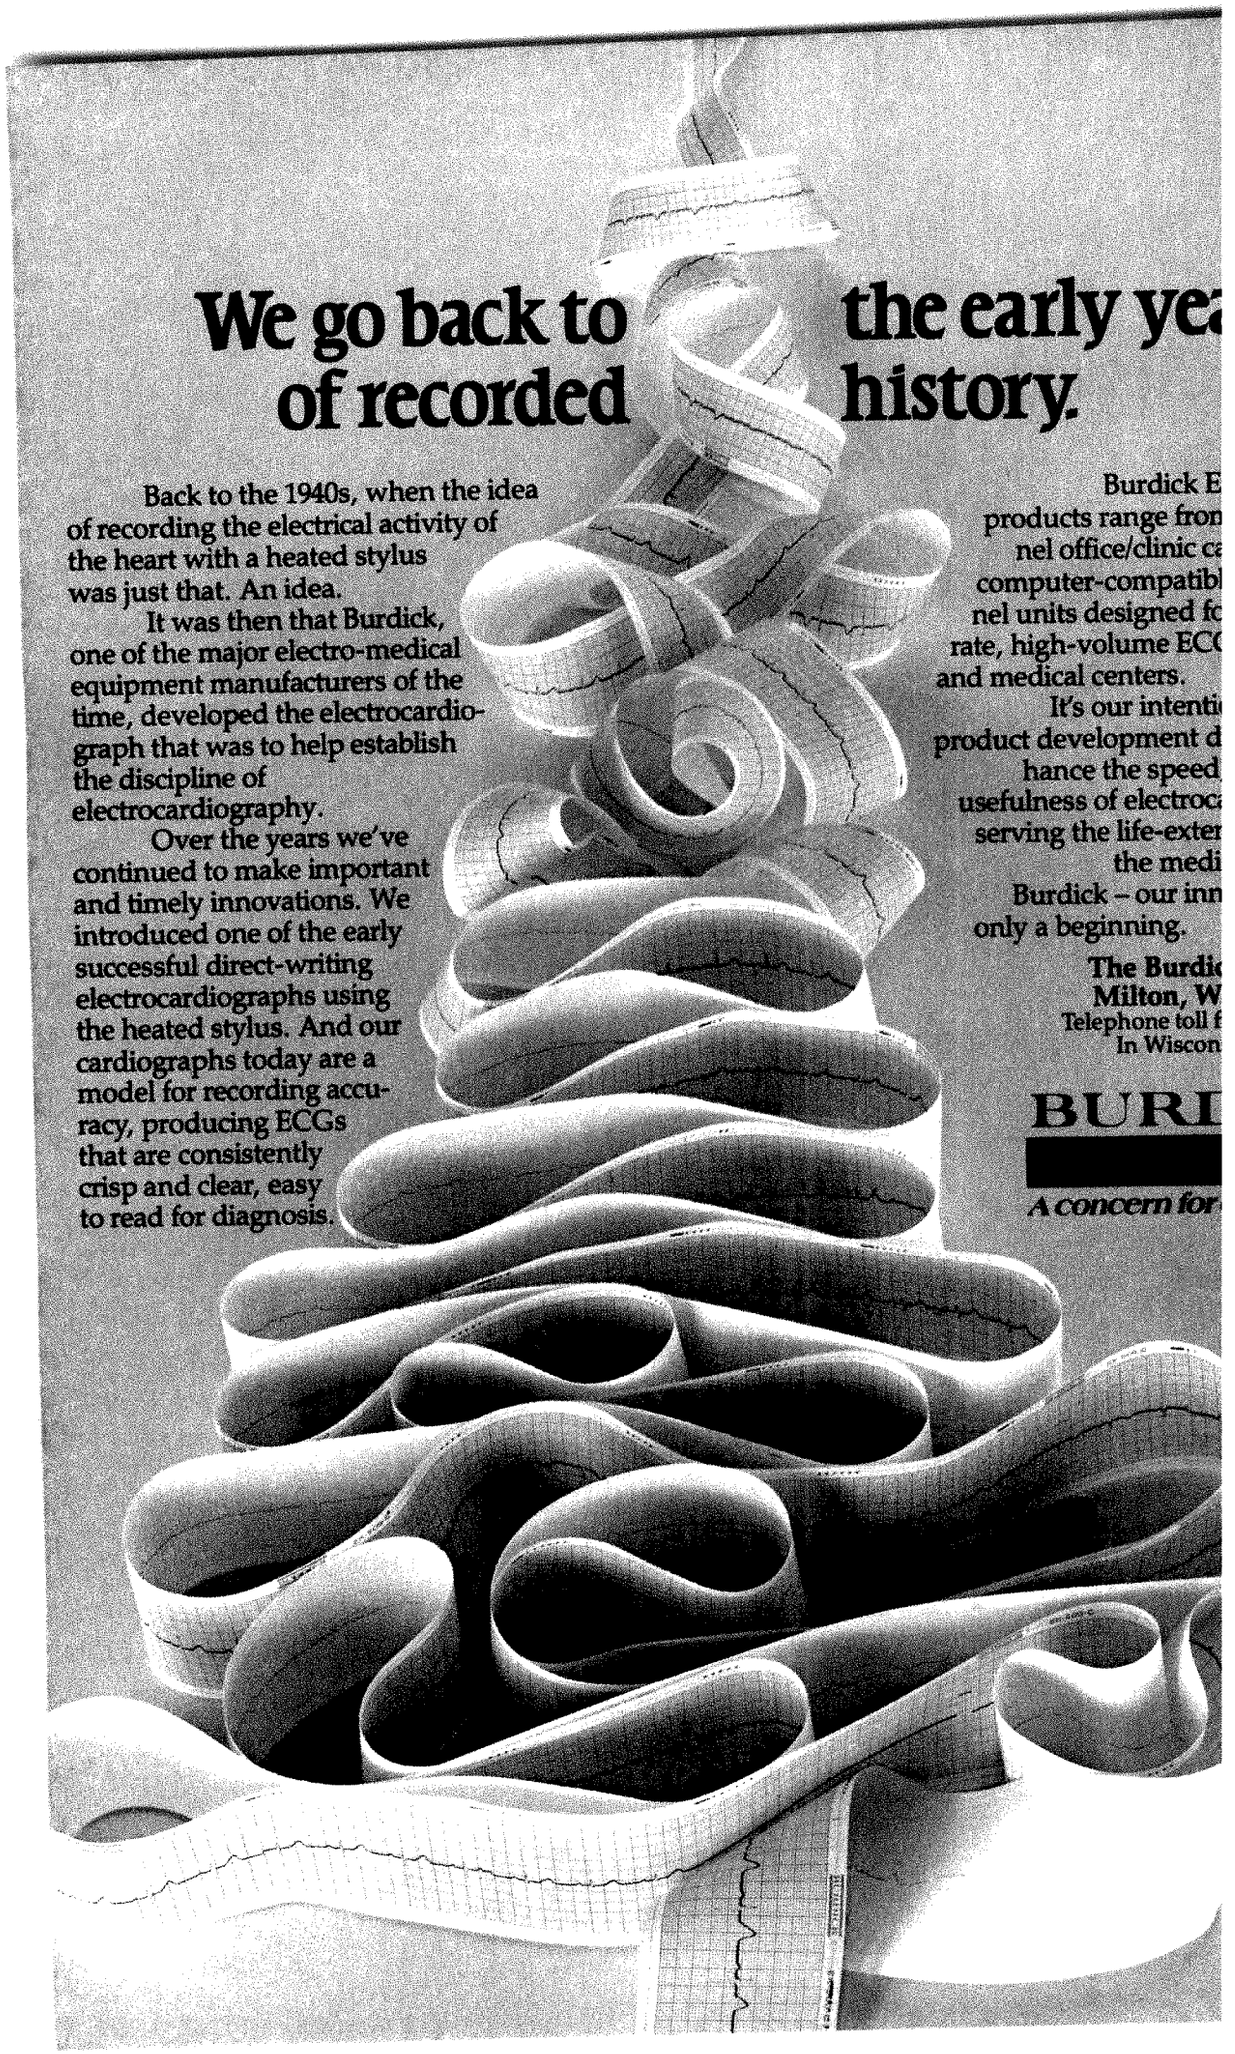
ISORDIL® TEMBIDS® Capsules
Sustained-Action Capsules, 40 mg

ndications: Based on a review of this drug by the National Academy of iences—National Research Council and/or other information, FDA has assified the indications as follows:
'robably" effective: When taken by the sublingual or chewable route, ordil Sublingual and Chewable Tablets are indicated for the treatment of cute anginal attacks and for prophylaxis in situations likely to provoke ich attacks.
'ossibly" effective: When taken by the oral route, Isordil is indicated for ie relief of angina pectoris (pain of coronary artery disease). It is not tended to abort the acute anginal episode, but is widely regarded as seful in the prophylactic treatment of angina pectoris.
nal classification of the less-than-effective indications requires further vestigation.

traindication: Idiosyncrasy to this drug.

rnings: Data supporting the use of nitrites and nitrates during the early s of the acute phase of myocardial infarction (the period during which clin- and laboratory findings are unstable) are insufficient to establish safety.

ecautions: Tolerance to this drug and cross-tolerance to other nitrites and rates may occur.



Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

We go back to the early yea
of recorded history.
Back to the 1940s, when the idea of recording the electrical activity of the heart with a heated stylus was just that. An idea.
It was then that Burdick, one of the major electro-medical equipment manufacturers of the time, developed the electrocardiograph that was to help establish the discipline of electrocardiography.
Over the years we've continued to make important and timely innovations. We introduced one of the early successful direct-writing electrocardiographs using the heated stylus. And our cardiographs today are a model for recording accuracy, producing ECGs that are consistently crisp and clear, easy to read for diagnosis.

VARIANT ANGINA PECTORIS AND SYMPATHETIC NERVOUS SYSTEM FUNCTION

obertson et al.[1] found no generalized increase in sympathetic utflow associated with the initiation of attacks of variant ngina and claimed that "germane to this discussion is the ffect of autotransplantation. This procedure has been investigated in the treatment of variant angina with one subject xperiencing relief of symptoms; nevertheless, the patient had ersistence of vasospasm in spite of the interruption of autonomic fibers to the coronary artery. . . . It may mean that he key to coronary vasoconstriction lies in local pathophysiology at the level of the vessel itself independent of central ympathetic outflow." I disagree with this interpretation for he following reasons: (1) The patient of Clark et al.[2] who had oral spasm of the right coronary artery responsible for severe ttacks had no recurrent attacks after autotransplantation. The patient was restudied after operation and spasm was gain demonstrated by the ergotrate stimulation test. The pasm observed after operation was provoked and not spontaneous. The woman has continued to do well 3 years after peration. (2) Recently Cipriano et al.[3] demonstrated that rgonovine maleate induced the same degree of coronary arterial narrowing in heart transplant recipients and in patients vith normally innervated hearts who did not manifest coronary spasm. Thus the normal pharmacologic response to ergonovine maleate was probably due to a direct vasoconstricting action of the drug and this action was independent f extrinsic neural control. (3) In our institution we performed utotransplantation in a man with severe variant angina. Before operation, the coronary arteriogram was normal and pasm of the left circumflex coronary artery was provoked by rgonovine. All drugs (nitrates, amiodarone, nifedipine, diltiazem) failed to obtain even slight relief of symptoms. In the 5 month follow-up period after cardiac autotransplantation vas performed, we observed the following: (a) The patient xperienced no chest pain (however, this finding is not significant because ischemic episodes can occur without pain and fter autotransplantation the paths of pain have been cut). b) Many continuous electrocardiographic recordings showed no S-T segment changes after operation, although such hanges had previously been observed. This finding suggests hat the ischemic episodes had been abolished. (c) On restudy rgonovine was able to reproduce spasm of the left circumflex oronary artery with electrocardiographic changes but without ain. This observation suggests that the coronary "trigger one" can be stimulated (by ergonovine) but is not spontaneously stimulated by the central nervous system. On the basis of the tests used in the study of Robertson et al. and on the basis of these considerations in relation to cardiac autotransplantation, we believe that it is inexact to deny a role to the central sympathetic nervous system.

Michael E. Bertrand, MD, FACC
Division of Cardiology B
Hôpital Cardiologique
Lille, France

REPLY

The careful follow-up Bertrand is undertaking—including repeated continuous electrocardiographic recordings—is critical to eventual understanding of coronary vasospasm. However, we continue to believe that the bulk of evidence supports the hypothesis that the primary abnormality in variant angina lies in the local vasculature rather than in the central nervous system.

Bertrand's patient, like that of Clark et al. (Bertrand's Ref 2), had excessive coronary arterial reactivity to ergonovine maleate both before and after effective autonomic denervation of the heart. Because denervation in itself does not cause excessive reactivity (Bertrand's Ref 3), it would appear that an abnormality independent of innervation exists.

It seems likely that in the presence of the primary vascular abnormality, diverse stimuli could lead to spasm. Ergonovine maleate is the best studied such stimulus, but we would not be surprised if circulating angiotensin, thromboxane A_2, vasopressin or the patient's own sympathetic nervous system might, under appropriate conditions, also serve as stimuli. It is important to recognize that such responsiveness need not imply abnormal levels of angiotensin, thromboxane A_2, vasopressin or adrenergic outflow.

The symptomatic relief achieved by autotransplantation thus far is heartening. The patient of Clark et al. is now doing well 5 years after surgery (Angell WW, personal communication), and Bertrand's patient has had no evidence of spontaneous coronary spasm detectable on electrocardiography. However, the cyclical nature of variant angina is such that remissions of years may occur[1] and optimism concerning this mode of therapy has to be tempered with caution.

Trials of inhibitors of potential stimuli such as angiotensin, thromboxane A_2 and norepinephrine will further our knowledge concerning the specificity of the vascular abnormality. Surgical interventions such as those of Bertrand are also pivotal in unraveling the mystery of this disease.

PLASMA PROPRANOLOL LEVELS IN ANGINA PECTORIS

Can the antianginal effects of propranolol be judged from its plasma concentrations? The duration of action of beta adrenergic receptor blockade has been disputed.[1–11] Previous investigators[1–5] have shown a dissociation between the rate of clearance of propranolol from blood and the slower disappearance of its effects. Thus, the longer duration of the action

of propranolol is somewhat puzzling, given its short elimination half-life.[12]

Whereas some investigators[6] believe that the hemodynamic duration of action correlates closely with serum levels of the drug, others[1-5] believe that the hemodynamic effects last considerably longer than the serum levels would indicate. Thadani and Parker[13] recently reported that, despite the short mean half-life of propranolol of 3.98 hours after the 80 mg dose and 4.28 hours after the 160 mg dose, the improvement in exercise tolerance and other circulatory effects persisted for 12 hours. They suggested that administration of propranolol twice daily should be adequate in treating patients with stable angina pectoris and concluded that routine measurement of plasma propranolol level is of little practical value in the management of such patients. I agree with their former suggestion but cannot agree with their latter conclusion for the following reasons:

According to a method proposed by Levy,[14] one can translate the pharmacokinetics of a drug to the pharmacodynamics. The effect (E) versus time data in the postabsorptive phase can be described by the equation[14]:

$$E = E_0 - \frac{m \cdot K_{el}}{2.3} \cdot t, \qquad (1)$$

where E_0 is the extrapolated zero time intercept and m is the slope of a plot of effect versus log plasma concentration (log C). This plot of concentration-effect relation is generally linear over the range of 20 to 80 percent of the maximal effect and can be represented by the equation[14]:

$$E = m \cdot \log C + r, \qquad (2)$$

where r is a constant.

When I use the average data of time course of plasma propranolol concentration (ng/ml) given in Table I of Thadani and Parker[13] and the corresponding data on percent increase in treadmill walking time to the onset of angina (P_1) after each dose of propranolol as one of the pharmacologic effects they examined during their experimental period (their Table II),[13] the average effect-concentration (log C) data were obtained as shown in my Figure 1. This relation was fit to a straight line ($E = 34.53 \cdot \log C - 9.96$, $r = 0.93$, $p < 0.001$) according to the equation (2) by linear regression analysis, where the value of the slope (m) was 34.53.

The mean elimination half-life ($t_{1/2}$) of 4.28 hours after the 160 mg dose[13] yields the elimination rate constant (K_{el}) of 0.162 hour^{-1}, which indicates that the disappearance rate of propranolol from the plasma as percent reduction per unit of time is 16.2 percent/h.

In contrast, when I use the observed data on percent increase in treadmill walking time to the onset of angina (P_1) after the 160 mg dose with time (as illustrated in their Fig. 2)[13] and calculate the correlation of the pharmacologic effect (P_1) with time from the linear decline 2 to 24 hours after oral drug administration, the following relation is obtained:

$$E = 65.08 - 2.41 \cdot t, \qquad (3)$$

where the value of 65.08 is the initial effect extrapolated from the linear decay of the effect with time at the zero order rate, and the value of 2.41 is the slope indicating the declining rate of drug effect in this case. When one estimates the declining rate of drug effect from this relation as percent reduction/h, the value of 3.7 percent reduction/h can be obtained. The effect declines linearly with time or at the zero order rate, even though drug level from the plasma falls exponentially or at the

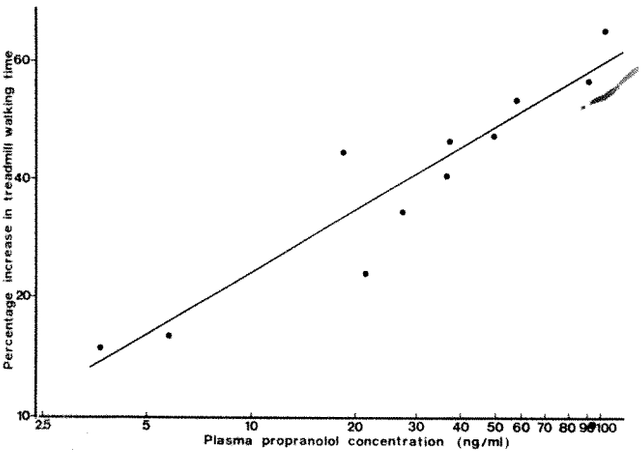

FIGURE 1. Relation between plasma propranolol concentration and percent increase in treadmill walking time to the onset of angina. The group mean values of plasma propranolol concentration (C) were obtained from Table I of Thadani and Parker.[13] The corresponding data of percent increase in treadmill walking time to the onset of angina (E) were calculated from the group mean values given in their Table II. The best fit of the solid line was: $E = 34.53 \cdot \log C - 9.96$ ($r = 0.93$, $p < 0.001$).

first order rate, and the duration of action of the drug is much longer (approximately 4.4 times) than the pharmacokinetic elimination half-life of propranolol. Furthermore, if one substitutes the values of m (34.53) and K_{el} (0.162 hour^{-1}) for $-m \cdot K_{el}/2.3$ in the equation (1), $E = E_0 - 2.43 \cdot t$ can be derived. The value of 2.43 generated from a theory of Levy[14] translating the kinetic data to the pharmacologic effect is very close to the actually observed value of 2.41. Thus, either as observed or as theoretically calculated, the 12 hour duration of action of propranolol observed by Thadani and Parker[13] is explainable by the shorter half-life of 4.28 hours after the 160 mg dose. Although I am analyzing all their data on circulatory effects (their Table II) in relation to plasma propranolol concentration (their Table I), it can be stated at present that the majority of their hemodynamic data can be predicted from the plasma propranolol concentration.

We recently observed that when we measured the beta blocking activity of timolol using maximal exercise tachycardia as a given response, the effects declined linearly with time, even though plasma levels fell exponentially, and thus demonstrated that the pharmacokinetic elimination half-life was much shorter than the drug's duration of action in normal human volunteers.[15] According to Perrier and Gibaldi,[9] it has been suggested on theoretical grounds that propranolol's action is related to a tissue level that equilibrates only slowly with the plasma level. However, our results[15] were in agreement with McDevitt and Shand,[10] who observed that the beta adrenergic blocking effect of intravenously administered propranolol was at all times a predictable function of its plasma concentration. In our dog experiments[16] with another beta blocking agent, sotalol, it was more clearly shown that pharmacokinetic data can be translated into pharmacologic effects by applying a theory developed by Levy.[14] The relation expressed in the equation (1) has interesting implications. It indicates that, despite a direct relation between drug concentration in plasma and intensity of the elicited pharmacologic effect, the rates of decline of these two quantities can follow different kinetics and, therefore, not be parallel. Furthermore, there was good agreement between such translated findings as the rate of decline of drug effect ($-m \cdot K_{el}/2.3$)

sing the slope of the log concentration-effect relation (m alue) and the first order rate of elimination rate constant K_{el}) and with findings actually observed in the time-action ourse of beta blockade as discussed earlier. Mayersohn and 'errier[17] recently proved that cocaine plasma concentration esponse time data analyzed by a pharmacokinetic model are n reasonable agreement with their application of Levy's heory[14] to actual published data.[18,19] This analysis is further upport for Levy's theory,[14] and our observations[15,16] strongly uggest that the significance of the kinetic disposition of a drug ıust be evaluated in relation to its pharmacologic effect and ime. However, because not only K_{el} but also m can vary to a ertain extent in a series of similar pharmacologic agents as bserved among different persons, there is a possibility of ıodifying the relation between the time course of the body rug content and the time-intensity course of a pharmacologic ffect.

Much discussion has focused on the possible therapeutic alue of the various ancillary pharmacologic properties of the eta receptor antagonists. However, Thadani and co-workrs[20,21] clearly demonstrated in their well controlled clinical rials using various beta receptor antagonists in patients with xercise-induced angina pectoris that these drugs with different pharmacologic properties were equally efficient in mproving exercise tolerance at their equipotent dose prolucing beta blockade effect. This indicates that the ancillary harmacologic properties are of little or no direct relevance n the relief of anginal pain but the beta blockade effect itself s of the most importance. Although their studies cannot upply a direct answer as to the specific importance of the nchanged agent or its metabolites[22,23] in the relief of angina, heir observation that similar symptomatic and electrocarliographic effects result after intravenous and oral adminisration in all instances implies some evidence that such meabolites are probably of therapeutic relevance only insofar s the drugs exert antagonistic action against endogenous ympathetic activity at the cardiac beta receptor sites.[20] Therefore, I assume that the beta receptor blockade itself is elated to the antianginal effect, which implies that the plasma evels of beta adrenoreceptor blocking agents should be apropriately interpreted. It is highly probable that the obserations of previous investigators[1–11] studying the relation etween plasma concentrations of beta blockers and the harmacologic effects are correct as experimental results but nay be incorrectly interpreted because they have not applied he appropriate principle for translating pharmacokinetics o pharmacodynamics of a drug.[14]

Finally, the relations between the logarithm of plasma oncentration and effect and effect and time must be taken nto account in order to interpret adequately the usefulness f determining the plasma level of the drug. It is evident that urther studies are required for such critical points before the lasma concentration of beta blocking drugs can become a herapeutic guide.

REPLY

Ishizaki has used our average data to examine the effect-concentration relation and found that the relation between the average percent increase in treadmill walking time to angina and the log plasma concentration fit to a straight line. Utilizing the theory proposed by Levy, translating the kinetic data to the pharmacologic effect, he has been able to explain the 12 hour duration of action of propranolol with its shorter elimination half-life of 4.28 hours after the 160 mg dose. We agree with his reasoning and conclusion that there was indeed a good effect-concentration correlation when one examines the average data. This was the case when we examined the relation between treadmill walking time to angina and plasma propranolol concentration. However, we would caution against utilizing the average plasma propranolol concentration in predicting a response in a given person because of the marked interindividual variations in plasma propranolol concentrations after a given dose reported by us and other workers. For this reason we correlated the effect-concentration relation in individual patients (our Fig. 4) and found a marked interindividual variation in effect-concentration relation. Furthermore, in many of the individual patients, increases in treadmill walking time to angina were similar when the plasma concentrations were above 50 ng/ml or below the level of detection by the analytic method employed. In view of these observations, we still believe that routine measurement of plasma

propranolol levels is of little value in the routine management of patients with angina pectoris.

HEART RATE RESPONSE TO ORAL PRAZOSIN IN PATIENTS WITH CHRONIC CONGESTIVE HEART FAILURE

Packer et al.[1] indicated a significant negative chronotropic action of prazosin in nine patients with severe chronic congestive heart failure. We recently evaluated the hemodynamic effects of 3 to 10 mg of oral prazosin in 15 patients with severe congestive heart failure. Although, at peak effect the change in cardiac index, left ventricular filling pressure and systemic vascular resistance in our patients was comparable with that found by Packer et al., the response of heart rate and systemic arterial pressure differed significantly. The decrease of mean blood pressure in our group after the administration of prazosin was significant but of lesser magnitude (-6.2 ± 2 mm Hg versus -18.3 ± 2.5 mm Hg). In contrast to the significant decrease in heart rate (from 84 ± 3 to 77 ± 4 beats/min, $p < 0.01$) found by Packer et al., the mean heart rate in our patients increased slightly (from 86 ± 4 to 89 ± 4), but the change did not reach statistical significance. Individual analysis of our data demonstrated a decrease of heart rate in only three patients, no change in four and an increase in eight patients. Because the mean dose of prazosin in our group was 6.6 mg compared with 5 mg administered by Packer et al. and seven of our patients received 5 mg or more, the described negative chronotropic effect of prazosin can not be interpreted as dose-related.

Mehta et al.[2] administered 4 mg of oral prazosin to 10 patients with congestive heart failure and showed a reduction of mean arterial blood pressure from 92 ± 5 to 78 ± 4 mm Hg ($p < 0.01$) but no significant change in heart rate. Miller et al.[3] described a tendency of the heart rate to decline after 2 to 7 mg of oral prazosin in 10 patients with congestive heart failure; however, this finding was not statistically significant. Whereas in hypertensive patients the negative chronotropic effect of prazosin is dissimilar to the tachycardiac effect of hydralazine, comparative evaluations of the hemodynamic effects of both drugs in the same normotensive patients with congestive heart failure showed no significant difference in heart rate response[4,5] We believe therefore that the overall information published to date does not allow the conclusion that prazosin exerts a direct negative chronotropic effect in patients with severe congestive heart failure.

REPLY

Not all studies on the hemodynamic effects of prazosin in patients with heart failure have described a decrease in heart rate during therapy. However, we are not alone in our observation; other investigators[1,2] have observed this type of response. Although Elkayam et al.[3] did not observe such an effect in their study, one major difference between their study and ours is that, although the average dose they evaluated was large (6.6 mg), this was not the first dose of the drug administered, as it was in our study; rather, all patients received 3 mg initially and were sequentially given larger doses until some patients received 10 mg. As with the other hemodynamic effects of prazosin, rapid tolerance to the negative chronotropic effects may develop with repeated administration of the drug.[4]

PROPRANOLOL AND ARRHYTHMIA IN HYPERTROPHIC CARDIOMYOPATHY

McKenna et al.[1] inferred that our statement[2] that "a daily dose of propranolol of less than 320 mg was rarely effective" was related to suppression of ventricular arrhythmias by beta blockade. They also implied that our use of large doses of propranolol was effective in suppressing complex ventricular arrhythmias. Our report emphasized the fact that daily doses of propranolol of more than 320 mg/day (average 462 mg/day) were necessary to achieve *"complete" beta blockade and symptomatic improvement* in most of our patients with hypertrophic cardiomyopathy. We did not state that propranolol was used primarily for elimination of arrhythmias. Propranolol doses greater than 320 mg/day were titrated by the symptomatic status of the patient. We suspected that *improved diastolic compliance* after propranolol therapy was responsible for the lessening of signs of congestive heart failure and dyspnea in our patients. Lessening of palpitations, presyncope and syncope appeared to have been related to arrhythmia control. However, antiarrhythmic agents *in addition to* propranolol were necessary in the great majority of our patients. Although we also had patients with arrhythmias, including short runs of ventricular tachycardia in the absence of symptoms, as well as patients with symptoms in the absence

of rhythm disturbances during ambulatory monitoring, the relation between suppression of potentially life-threatening arrhythmias and symptomatic improvement was striking. Potentially life-threatening arrhythmias were suppressed in all but one patient who had residual rare couplets only; palpitations and presyncope lessened in most; syncope was eliminated in all, and there have been no deaths.[3]

Regarding the antiarrhythmic properties of propranolol, our manuscript clearly indicates that potentially life-threatening arrhythmias were controlled with propranolol in only 4 of 11 patients; the addition of other antiarrhythmic drugs was necessary in the remainder.[2] This was also the case in our larger group (33 patients).[3,4] We found that control of 77 percent of complex forms of arrhythmia required other antiarrhythmic drugs in addition to propranolol. However, in 21 percent frequent premature ventricular complexes (grade 2 of Lown's classification[5]) *without complex forms* decreased in frequency to grade 1 or 0 with propranolol alone. Woosley and his associates[6] recently reported on the use of propranolol as an antiarrhythmic drug. They found that ventricular arrhythmias including ventricular tachycardia responded in one third of 32 patients at doses of 160 (or less) mg/day, but an additional 40 percent responded at doses of 200 to 640 mg/day. They also found that some patients with partial or complete suppression of ventricular arrhythmias at a given dose of propranolol had an increase in arrhythmia severity when the dose was increased. Therefore, it is not surprising that some of the patients of McKenna et al. had arrhythmias even on a regimen of 800 mg/day of propranolol, since larger doses do not invariably produce better results. It appears that control of malignant ventricular arrhythmias requires more than one antiarrhythmic agent in the great majority of cases, as also reported by Lown et al.[5]

We postulate that beta blocking doses of propranolol should be used in *all symptomatic patients* with hypertrophic cardiomyopathy because of this drug's value in controlling symptoms, presumably by improving diastolic compliance. In addition, we believe that our routine use of propranolol may have prevented the onset of atrial fibrillation[3] and *contributed* to the control of ventricular arrhythmias when used with other antiarrhythmic agents.

REPLY

We appreciate that Frank et al. used propranolol primarily for its hemodynamic and symptomatic benefits; this is clearly stated in their paper. Their comments on the possible benefits of propranolol related to arrhythmia control are somewhat ambiguous, however. We quote: "Because there have been no fatalities in our 22 protocol patients . . . we suspect that high doses of propranolol alone may have been responsible for controlling life-threatening arrhythmias." And: "In contrast to our experience Ingham et al. reported that propranolol was not effective as an antiarrhythmic agent in patients with . . ." We entirely agree with the conclusion of Frank et al. that beta blocking doses of propranolol should be used in symptomatic patients for relief of symptoms, but we have no evidence in our patients that propranolol prevented the onset of atrial fibrillation. Propranolol may indeed help to control arrhythmias when given with other antiarrhythmic agents, but we do not have the proof.

MYOCARDIAL BRIDGING AND IDIOPATHIC HYPERTROPHIC SUBAORTIC STENOSIS

Several workers[1,2] have recently reported septal perforator compression, especially in idiopathic hypertrophic subaortic stenosis. We noticed septal perforator compression 1 year ago in a patient who had idiopathic hypertrophic subaortic stenosis and myocardial bridging of the left anterior descending coronary artery. Since then, a coronary arteriogram was obtained systematically in the 12 patients in the department who were hospitalized for idiopathic hypertrophic subaortic stenosis. From 1974 to 1978, seven other arteriograms had been performed in cases of idiopathic hypertrophic subaortic stenosis. We compared the results of these 19 arteriograms with those of 16 patients with aortic stenosis: All patients with idiopathic hypertrophic subaortic stenosis had a significant (30 mm Hg or greater) intraventricular pressure gradient at rest or on provocation with isoproterenol or premature ventricular depolarization (average 79 mm Hg). Eighteen patients had a characteristic left ventricular angiographic pattern together with typical phonocardiographic and carotid pulse curves. An echocardiogram obtained in 16 of these cases was diagnostic of idiopathic hypertrophic subaortic stenosis in 15.

We found myocardial bridging of the left anterior descending coronary artery in five patients with idiopathic hypertrophic subaortic stenosis (26.3 percent), whereas the frequency of myocardial bridges in large series of coronary arteriographic studies is estimated to be between 0.1 and 0.7 percent. We found no myocardial bridge in any of the 16 patients with aortic stenosis.

Unlike Pichard and Kostis and their co-workers, we did not find systolic compression of the septal perforator arteries in all, but in 12 cases of idiopathic hypertrophic subaortic stenosis (63.2 percent). Like Pichard,[3] we noticed septal perforator compression in only one case of aortic stenosis (5 percent in our series). The reasons for the discrepancy on this point between the results of Pichard and our group and those of Kostis are not obvious.

We found no statistically significant correlation between the degree of septal perforator compression and either the hemodynamic (especially the intraventricular pressure gradient) and echocardiographic features or the presence of angina in patients with idiopathic hypertrophic subaortic stenosis.

The role of myocardial bridging in myocardial ischemia was

l demonstrated by Noble et al.[4] Finding it in a case of idathic hypertrophic subaortic stenosis, especially in assotion with a severe septal perforator compression, is for us rther argument for carrying out an effective beta adrenic blocking regimen. Therefore, coronary arteriography uld be an indispensable step in any complete investigation diopathic hypertrophic subaortic stenosis.

amaguchi H, Ishimura T, Nishiyama S, et al. Hypertrophic nonobstructive cardiomyoathy with giant T waves (apical hypertrophy): ventriculographic and echocardiographic ıatures in 30 patients. Am J Cardiol 1979;44:401–12.

IRE 1. Apical hypertrophic cardiomyopathy. End-diastolic frame from a two dimensional ıcardiogram at the level of the papillary muscles (short-axis view). The thickness of the septum and the posterior free wall is markedly increased. The papillary muscles ılso hypertrophied. Obliteration of the apical cavity is clearly demonstrated. APM = ·olateral papillary muscle; PPM = posteromedial papillary muscle.

REPLY

The source of the multiple echoes in the M mode echocardiogram of the left ventricle has generally been thought to be the papillary muscles.[1] In the cases of apical hypertrophic cardiomyopathy we presented, the posterior wall thickness may include some parts of the papillary muscles. The obliteration in the apical cavity is therefore composed of the hypertrophied papillary muscles muscles as well as the hypertrophied septum and posterior wall (Fig. 1).[2–5]

Two dimensional echocardiography also suggests that hypertrophied papillary muscles are related to the apical obliteration. However, M mode echocardiography sometimes makes it difficult to obtain and record the maximal internal dimension of the left ventricle during the scanning and may artificially produce a false apical obliteration even in normal subjects. It is therefore necessary to use two dimensional echocardiography as well as simultaneous M mode echocar-

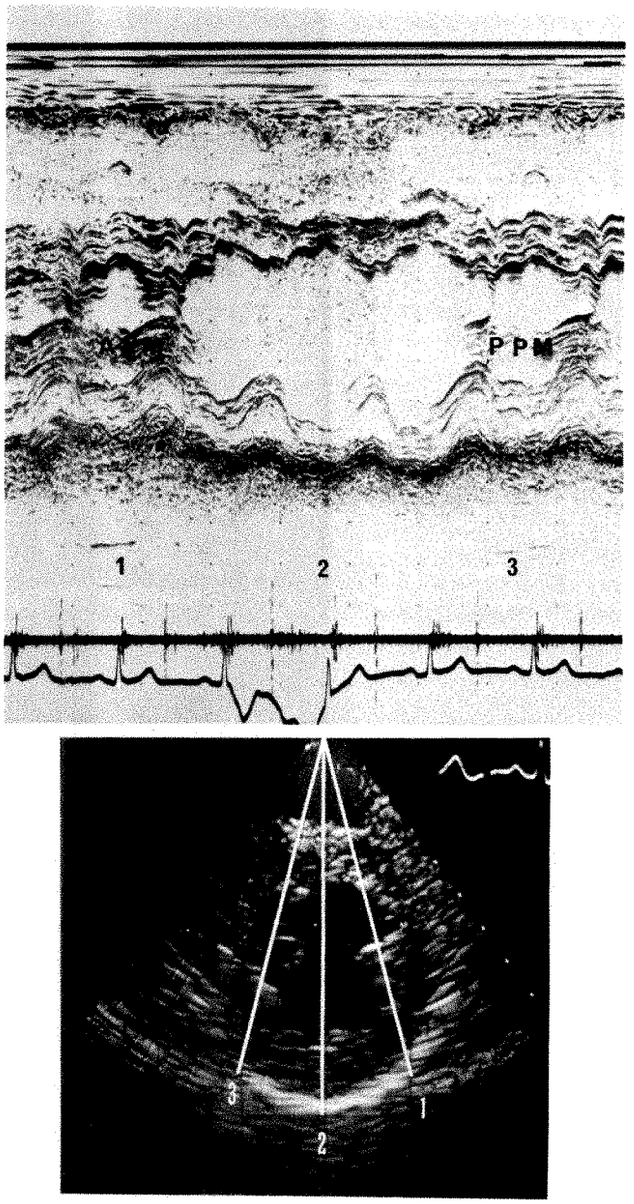

FIGURE 2. M mode (**top**) and two dimensional (**bottom**) echocardiogram simultaneously recorded in a normal subject. The echoes of the papillary muscles appear to produce a false cavity obliteration in the apical segment.

diography for evaluation of hypertrophic cardiomyopathy (Fig. 2). We believe that cineangiographic confirmation of ventricular morphology is even more important in obtaining a definite diagnosis of apical hypertrophic cardiomyopathy. The cineangiogram can clarify the hypertrophic pattern of the apical segment as well as the presence or absence of coronary artery disease.

FORMAL CARDIAC REHABILITATION

I am concerned that the article by DeBusk et al.[1] may give the impression that a formal cardiac rehabilitation program may be without benefit for many patients recovering from an acute myocardial infarction. Follow-up data collected from patients recovering from an acute myocardial infarction who were hospitalized at Cedars-Sinai Medical Center, Los Angeles and who did not enter a formal cardiac rehabilitation program showed the following:

1. The percent of patients who engaged in unrestricted physical activities before and after acute infarction was 54 and 11 percent, respectively.

2. The percent of patients who engaged in moderate activity (walking 1 or more miles daily, and maintaining unrestricted social and occupational activities) before and after acute infarction was 21 and 33 percent, respectively.

3. The percent of patients who were sedentary (performing only routine household chores and engaging in no unusual physical activities) before and after acute infarction was 13 and 35 percent, respectively.

4. The percent of patients who were restricted (not able to perform routine household activities) before and after acute infarction was 6 and 16 percent, respectively.

5. Overall, 6 percent of patients increased their activity level after an acute infarction, 41 percent showed no change and 53 percent decreased their activity.

Thus, among our patients who did not undergo formal cardiac rehabilitation, over one half became either sedentary or restricted in activity. With formal rehabilitation, only 11 percent of patients were in these activity classifications. To base conclusions on a study in which the average "no training" patient was walking an average of 3 miles/day may not be valid, because in our experience 51 percent of postinfarction patients become either sedentary or restricted in activity. Formal cardiac rehabilitation programs have many benefits. Not least among them is that they motivate postinfarction patients who would otherwise become sedentary or restricted in activity to a greater level of physical exertion under close supervision from which, presumably, flow the benefits, including a longer life for the average patient in such a program.[2] The low level home exercise programs suggested by De Busk and colleagues as an alternative to formal cardiac rehabilitation appear to be suitable for only a small minority of such patients, since 94 percent of patients without formal training show either no change or decreased activity after acute infarction.

Most patients probably are less physically active after myocardial infarction, and Vyden properly points out that our "no training group" was not truly a control group in the sense that patients underwent an intervention—treadmill exercise testing—as a prerequisite for entry into the study. Indeed, such patients reported walking considerable distances each day. And this is one of the major points we wished to make: Performance of the treadmill test in itself appears to increase patients' confidence in their capacity to perform physical activity and they become more active than they would have been without the test. Is this not "formal rehabilitation"? If it is safe for selected patients to walk 3 miles/day and if there are potential psychological and physical benefits to be had from this cost-free, readily available activity, how "formal" does rehabilitation need to be?

The primary objective of our study was to establish whether a relatively low level, short-term exercise training program, commencing soon after the acute event, would significantly augment the substantial increase in functional capacity that occurs spontaneously after clinically uncomplicated myocardial infarction. The increase in functional capacity was found to be greater in patients without ischemia who underwent exercise training in a supervised gymnasium program than in similar patients who received no formal training. Similarly, patients without ischemia who underwent home exercise training attained a higher absolute functional capacity at 11 weeks than similar patients who received no formal training. These differences, although *statistically* significant, may have marginal *clinical* significance, because all patient groups attained an average functional capacity of at least 9 METs by the 11th week after infarction. A functional capacity of 8 METs is considered an *"exit criterion"* for cardiac exercise training programs.[1] Such patients would be capable of performing most vocational and avocational activities.[2]

Our study thus demonstrates physiologic benefits for *both* gymnasium and home exercise training programs commencing soon after clinically uncomplicated myocardial infarction. Our study addressed only the short-term effects of exercise training on cardiovascular performance, not the impact of training on psychological status or prognosis. No one should conclude from our study that formal rehabilitation programs are without benefit.

Yet it is clear that rehabilitation programs as presently constituted can accommodate only a small minority of postinfarction patients. A rough estimate of the gap between the demand for and the supply of such programs is as follows: 600,000 persons survive myocardial infarction each year; at least two thirds of them—400,000—are free of major complications and therefore medically eligible to participate in exercise training programs. If one assumes that only persons aged 70 or less participated, 300,000 patients would be avail-

ible to enter medically supervised exercise training programs. Existing programs in the United States accommodate no more than 200,000 patients with coronary disease annually. If the capacity of such programs were increased 50 percent by reducing the duration of participation, the entire capacity of these programs would be absorbed by postinfarction patients, leaving no room for patients with angina pectoris or those who have had coronary bypass operations. The problem does not stop there, because a sizable proportion of postinfarction patients reside in communities that are too small (less than approximately 100,000) to support group training programs. Further, even where programs are available, many patients cannot afford to participate for financial or logistic reasons.

Thus, group programs can meet only part of the need to provide "formal rehabilitation." Other approaches are needed to facilitate the return to normal physical activities after myocardial infarction. It is not surprising that patients become less active after infarction: They and their physicians lack information concerning their safe level of activity. Even a low level of effort, such as walking at a rate of 2 to 3 miles/h (2 to 3 METs), represents an advance over the present circumstance in which many patients are unnecessarily restricted soon after infarction. A treadmill exercise test helps to provide assurance that this level of effort is safe for a given patient. Whether the physiologic benefit of exercise training at a level more intense than walking justifies the risk and the cost of formal programs remains to be established. In summary, we believe it is too early to conclude that only formal group programs of rehabilitation can meet the needs of patients recovering from myocardial infarction.

EFFECTS OF ANTIHYPERTENSIVE THERAPY ON CARDIOVASCULAR RESPONSE TO EXERCISE

The effect of various antihypertensive drugs on blood pressure control during exercise is an area not quite as neglected as apparent from the article by Lee et al.[1] In our laboratory we have systematically studied the long-term hemodynamic effects at rest and during exercise of the following antihypertensive drugs: hydrochlorothiazide, polythiazide, chlorthalidone, alpha methyldopa, clonidine, prazosin, six different beta blocking agents and labetalol. It is true that blood pressure control during exercise often differs from that during rest, and there are large differences in the hemodynamic mechanisms behind the reduction in blood pressure. A relatively recent review (with 106 references) is found in Reference 2. Many papers on hemodynamic effects include observations during exercise. Exercise studies of more recent antihypertensive agents, such as bunitrolol and labetalol, are found in References 3 and 4.

SYSTOLIC HYPERTENSION IN THE ELDERLY—I

Simon et al.[1] present an interesting study on the difference in mechanisms of systolic hypertension in younger and older patients. Given the different mechanisms, the difference in response to propranolol and nitroprusside in the two groups would certainly be expected. However, I disagree with their conclusion that older patients with isolated systolic hypertension should be treated with vasodilators. It certainly has been well demonstrated that systolic hypertension, especially in the elderly, is correlated inversely with survival,[2] but to my knowledge there are no studies that show that treating systolic hypertension in the absence of diastolic hypertension lessens morbidity and mortality. The major cause of systolic hypertension in older patients appears to be atherosclerotic noncompliant vessels, and treating that problem as such cannot be done. Furthermore, the therapy of systolic hypertension may decrease diastolic pressures to levels lower than desired, resulting in lower perfusion pressures than desired. This, of course, could be particularly deleterious in older patients with coronary artery disease. Older patients are also prone to the development of symptoms of orthostatic hypotension, and antihypertensive medications in older patients with isolated systolic hypertension may exacerbate these symptoms. Therefore, I believe that older patients with systolic but without diastolic hypertension should generally not be treated with antihypertensive medications.

SYSTOLIC HYPERTENSION IN THE ELDERLY—II

We are especially interested in the suggestion of Simon et al.

that "nitroprusside-like" drugs might prove successful in controlling systolic hypertension in the elderly. However, certain of their findings are puzzling: (1) In the older patients receiving nitroprusside, the total peripheral resistance increased. Although this increase was statistically nonsignificant, it is difficult to interpret in light of the known action of nitroprusside: arteriolar dilatation. (2) The authors refer to the effect of nitroprusside-like drugs on compliance of the aorta without giving examples of such drugs. How do the authors explain the increase in peripheral resistance, and which nitroprusside-like drugs would they recommend for therapy?

REPLY

The purpose of our study was to determine the mechanisms of systolic hypertension in younger and older patients. Drugs were used to confirm the described mechanisms. Because nitroprusside was given intravenously to our patients, we mentioned the use of vasodilating drugs to treat systolic hypertension in the elderly only as a possibility. However, several recent studies provide indirect evidence supporting the possibility of such treatment.

Epidemiologic studies[1–4] have shown that systolic hypertension, especially in the elderly, is correlated inversely with survival. The Veterans Administration Cooperative Study group,[5] evaluating the influence of age on the effectiveness of antihypertensive treatment, found that in patients more than 60 years of age the rate of morbid events was 62.8 percent in the control group and 28.9 percent in the treated group. Subsequently, the effectiveness of treatment in preventing morbid events (that is, the difference between the incidence rate of major complications in the control and treated groups divided by the incidence rate in the control group) was 54 percent in the patients aged 60 or more years. More recently, the side effects of antihypertensive therapy in patients more than 60 years of age were extensively studied by the European Working Party on High Blood Pressure in the Elderly.[6,7] During a 2 year follow-up period, the antihypertensive treatment had no major deleterious effects in relation to coronary heart disease or orthostatic hypotension. The main disturbance was an increase in serum creatinine and uric acid that was maintained for 2 years. Because the antihypertensive drugs were hydrochlorothiazide, triamterene and methyldopa,[7] the results of the study suggest that new types of treatment for the elderly should be of interest.

Several vasodilating drugs have recently been proposed for use in clinical pharmacology. Most of them have minimal secondary effects on the sympathetic nervous system. If they could increase arterial compliance, their antihypertensive effect in the elderly should be considered. Table I shows, for example, the changes in systolic pressure observed after intravenous nitroglycerin in patients with hypertension.[8] Both in patients with borderline and in patients with sustained hypertension, a significant increase in arterial compliance was observed. In patients with borderline hypertension, this increase was associated with an important baroreflex response, causing an elevation in heart rate, diastolic pressure and total peripheral resistance, as described in detail elsewhere.[8] In patients with sustained hypertension, the increase in compliance was not associated with a significant change in total peripheral resistance. This peculiar effect was due to the use of small doses of nitroglycerin. Similarly, we used small doses of nitroprusside in our study of systolic hypertension. With such doses, it is possible to show the direct effect of vasodilating drugs on large arteries and the resultant predominant decrease in systolic pressure. Of course, with larger doses, arteriolar dilation occurs, causing a decrease in both systolic and diastolic pressures.

LEFT ANTERIOR FASCICULAR BLOCK AND INFERIOR MYOCARDIAL INFARCTION

The results of Fisher et al.[1] describing scalar electrocardiographic criteria for the concomitant presence of left anterior fascicular block and inferior wall myocardial infarction are encouraging to students of deductive electrocardiography and Grant's spatial vector method.[2] The diagnosis of inferior myocardial infarction with concomitant left anterior fascicular block by vectorcardiographic criteria is dependent on reversal of QRS loop rotation to counterclockwise beyond the 40 ms QRS instantaneous vector.[3] False positive electrocardiographic diagnoses of left anterior fascicular block in patients with only inferior myocardial infarction by vectorcardiography may occur with the criteria proposed[1] because loop rotation—a vectorcardiographic criterion for left anterior fascicular block—cannot be easily translated into routine scalar electrocardiographic terms.

I have observed patients whose studies satisfied quantitative vectorcardiographic criteria for inferior myocardial infarction[4] who have left axis deviation on electrocardiography, a terminal positive deflection (r wave) in lead aVR, a terminal negative deflection (S wave) in leads II and aVF and whose entire QRS loop in the frontal plane on Frank vectorcardiography rotates clockwise (Fig. 1 and 2)! All of these persons had morphologic QRS complexes in leads II and aVF although mean and maximal amplitude QRS vectors were all negative and less than 25°, respectively, in the frontal plane.

Deductive electrocardiography, such as that utilized by Fisher et al. in the formulation of their "hypothesis," would have predicted that in all these persons the depth of the S wave should have exceeded that of the Q wave in the complexes of lead II. By similar reasoning, an RSr′ rather than an rSR′ or QR complex should have occurred in lead aVR, allowing differentiation of such troublesome cases. Neither of these hypotheses was dependably correct, probably because of the assumptions inherent in the hexaxial reference system as defined by the Einthoven triangle. The standard and augmented limb leads are not pure "frontal plane leads," as torso studies have revealed.[5]

What appears to be valid, however, is that in those cases with a false positive diagnosis of left anterior fascicular block by the electrocardiographic criteria of Fisher et al., the width (duration of inscription in the vectorcardiogram) of the Q wave in leads II and aVF is greater than that of the terminal S wave in these leads (Fig. 1). This would appear to occur only when QRS loop rotation in the frontal plane beyond the 40 ms vector remains clockwise (Fig. 2). Perhaps the criteria recently published for concomitant left anterior fascicular block should be further revised to exclude such rare cases by imposing the further restriction that the "deep terminal S wave in lead II must be wider than any preceding Q wave in that lead."

REPLY

It should be emphasized that the false positive pattern illustrated is relatively *rare*. Zema's suggestion of using both width and depth criteria for analyzing the terminal S wave in lead II should help to make our proposed criteria more specific. Total specificity cannot be anticipated until there are well established and unequivocal standards for the recognition of left anterior fascicular block.

ELECTROCARDIOGRAPHIC PSEUDOINFARCTION PATTERN WITH PERICARDIAL EFFUSION

Salem and colleagues[1] described two patients with a large posterior pericardial effusion associated with electrocardiographic Q waves that disappeared after clearance of pericardial fluid. Although myocardial infarction was excluded in each case no precise explanation could be offered for the phenomenon but it was thought that changes in electrical conductivity and orientation of the heart within the pericardial sac in the presence of pericardial fluid might be responsible. These two cases were apparently the first reported illustrated examples of the occurrence of Q waves in this situation.

These two cases reminded me of a not dissimilar case that Levison and I[2] reported in 1976.

Case report: A 14 year old Scottish boy was found to have a large heart shadow on a chest radiograph taken because of contact at school with a child with tuberculosis. A presumptive diagnosis of tuberculosis pericardial effusion was made and he was admitted to the hospital. His symptoms were dry cough, retrosternal discomfort, anemia and occasional vomiting during the preceding week only. The electrocardiogram on admission is shown in Figure 1, top. Treatment with rifampicin, ethambutol and isoniazid was begun but on the 6th day after admission he became dyspneic and cyanosed. Cardiac tamponade was apparent clinically. One liter of blood-stained pericardial fluid was aspirated using an anterior approach. Within hours of aspiration the patient's condition deteriorated.

A second electrocardiogram revealed Q waves in leads I, aVL and V_2 to V_3 (Fig. 1, bottom). In the belief that further hemopericardium may have been induced by needle trauma during aspiration, a further aspiration was attempted and 300 cc of sanguinous pericardial fluid was aspirated with no clinical benefit. The patient died 10 hours after the initial aspiration despite attempts at resuscitation.

The case was of particular interest because the patient proved at necropsy to have a primary angiosarcoma of the right atrium and was younger than any previously reported patient with this finding. Moreover, histologic study showed the sarcoma to be of the Kaposi type. The electrocardiographic changes, although mentioned, were not illustrated in the paper. There was no evidence of coronary occlusion at necropsy and I believed the electrocardiographic changes were

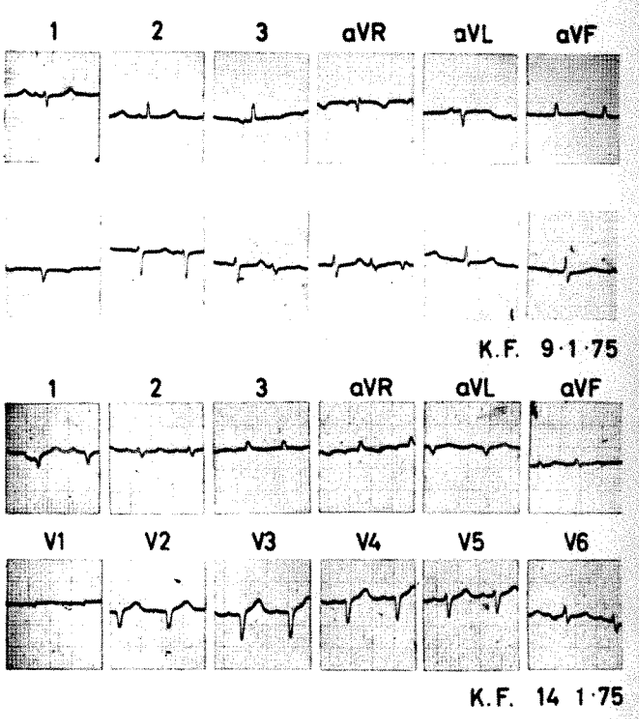

FIGURE 1. Electrocardiograms. **Top,** on admission to hospital when patient presented with pericardial effusion. Appearances are normal apart from some multifocal ectopic complexes. **Bottom,** after aspiration of one liter of pericardial fluid showing development of Q waves in leads I, aVL and V_2 to V_3.

probably due to major positional changes incurred by the removal of 1 liter of pericardial fluid. The electrocardiographic changes in this patient are very similar to those of Patient 1 of Salem et al. Interestingly, whereas in the American cases, Q waves disappeared after aspiration, in the Scottish case Q waves developed after aspiration. Unlike the American patients our patient had an extensive and not a localized posterior effusion.

Being a respiratory physician rather than a cardiologist I would not presume to offer explanations for the development of Q waves with pericardial effusion. However, I trust that Salem and associates will be interested to read of my case and will not be aggrieved if I proffer that the association had previously been noted.

REPLY

We were interested to learn of this case, and not aggrieved by the claim that the association of Q waves and pericardial

effusion had previously been noted, because it is inaccurate.

In their description of the electrocardiographic changes Levison and Semple stated: "By this time Q waves had developed in the chest leads V1–V4 of the electrocardiogram, suggesting coronary occlusion as another possible cause of enzyme rise." Nowhere in the discussion is the possibility of the effusion being responsible for the Q waves mentioned; the electrocardiographic changes occurred after a traumatic pericardiocentesis and, even though coronary occlusion is implied, there is no description of the coronary arteries in the anatomopathologic report.

The context of the letter submitted to you is clearly different from that of the article. If in retrospect Semple believed that the electrocardiographic changes were probably due to major positional changes incurred by the pericardiocentesis, he failed to discuss it in his article.

DRAINAGE OF PERICARDIAL EFFUSION

The exchange of letters over "medical" vs. surgical drainage of pericardial effusion by Becker, Achuff and Wei[1] sheds considerable light on the approach to management of a first class emergency—cardiac tamponade. I have been doing pericardial catheterization drainage for over 20 years[2–4] and, although in two cases a ventricle was entered, I have been fortunate to have had no mishaps (although an occasional "dry tap"). This may be due to luck or to the prevalence of very large effusions, which are easier to drain. I also prefer to aim for the left rather than the right shoulder and to proceed in a very slow, worm-gear motion as outlined elsewhere.[5]

I think all points made by both "opponents"[1] are valid and that, despite my own good luck, a limited subxiphoid surgical approach is probably optimal. When one does not have sufficient time and the situation is deteriorating rapidly, a needle pericardiocentesis must be done. I would only plead that the catheterization technique be used always, because once you are "in," a relatively soft catheter rather than a hard needle is pointed at the heart. On the other hand, I must disagree strongly with Becker's citation of the report by Kilpatrick and Chapman[6] as providing competent evidence. This was, indeed, an interesting, largely historical account. That part of it from their personal experience involved only 12 cases, in which the only death occurred in a patient with malignant invasion of the pericardium immediately after instillation of nitrogen mustard into the pericardial space—certainly not a complication of the tap itself. The authors make the incomprehensible statement: "Probably most attempts at pericardiocentesis have gone unrecorded unless they provide diagnostic information of dramatic input. Unsuccessful attempts, and not infrequently complications, may also fail to find their way into hospital records."[6] Plainly, this will not do. It is conjecture and not supported by a scintilla of evidence. Routine practice in any decent hospital is to record and note the details of all procedures. This is surely the standard in teaching hospitals and the report of Kilpatrick and Chapman is from a teaching hospital. In any case, even these authors agree to pericardial puncture when "time is of the essence." Moreover, large effusions are relatively easy to tap and should provide no difficulties for those willing to apply the exquisite care and patience necessary to avoid mishap.[5]

POSTOPERATIVE CONSTRICTIVE PERICARDITIS

In their report of three cases of constrictive pericarditis after myocardial revascularization Marsa and colleagues[1] present well formulated conclusions regarding the role of povidone-iodine solution (Betadine®). In light of the appearance of these cases after the routine use of Betadine, it was reasonable to assign it a role in producing constriction. Previous work supports the role of the iodine moiety of Betadine. At least 28 agents or procedures have been employed to cause experimental pericardial scarring.[2] These data include the early work of Beck and Moore[3] and Musser and Herrmann,[4] who used iodine tincture to produce pericardial adhesions.

REPLY

We appreciate Spodick's considerate and informative observations. Also we wish to draw attention to Cohen and Greenberg's report[1] of postoperative constrictive pericarditis, published after submission of our manuscript.

Two additional cases of surgically confirmed postoperative constrictive pericarditis have been seen by our group: *Case 1:* Nine months after an uncomplicated pulmonary commissurotomy performed in Saudi Arabia by members of our surgical team, an 18 year old Saudi Arabian youth presented with right heart failure (mean right atrial pressure 20 mm Hg)

and a right pleural effusion. He was successfully reoperated on in February 1979, with decortication of very adherent, densely fibrous tissue encompassing the heart and adjacent great vessels. It is not known whether he had had intraoperative pericardial irrigation with povidone-iodine solution at the time of his original operation. There was no evidence of tuberculosis.

Case 2: In a 9 year old Korean girl with tetralogy of Fallot, bilateral pleural effusions developed 10 days after corrective surgery performed at this institution in January 1980. She was afebrile. Increasing evidence of right heart failure led to cardiac catheterization (intracardiac diastolic pressures were approximately 20 mm Hg) and to surgical exploration 4 weeks postoperatively. Surgery revealed loculated pericardial fluid with a severely adherent pericardium, which was removed anteriorly. Recurrent right heart failure and pleural effusions led to reexploration 5 days later, with discovery of a newly formed, dense epicardial peel. Decortication was followed by immediate improvement in the patient's hemodynamics and a subsequently uncomplicated course. Histologically the surgical speciman showed dense fibrosis and areas with possible talc crystals and foreign body giant cells. The pericardium had not been irrigated with povidone-iodine.

The addition of these two cases to previously reported cases of constrictive pericarditis after cardiac surgery gives a total of 19. It is possible that as awareness of this entity increases it may prove to be more frequent than previously thought.

JUNCTIONAL ECTOPIC TACHYCARDIA IN INFANTS

I have been treating an 8 month old male infant with junctional ectopic tachycardia whose clinical course contrasts sharply with that of the patients described by Garson and Gillette.[1] The infant had an uneventful gestation and a normal spontaneous delivery. At age 2 days his heart rate ranged from 200 to 230 beats/min. An electrocardiogram (Fig. 1) demonstrated junctional tachycardia with occasional capture beats. Neither digitalization nor administration of propranolol (3 mg/kg daily) altered the rhythm. The infant was discharged from the hospital without medication. Although he had continuous junctional tachycardia, he remained asymptomatic and grew normally until age 3 months when he was hospitalized for an elective inguinal herniorrhaphy. Premedication was not given; anesthesia was induced with halothane by mask. While being intubated he manifested ventricular tachycardia (rate 240 beats/min). He was immediately given 100 percent oxygen, and the arrhythmia reverted to junctional tachycardia in about 15 seconds. Induction of anesthesia with halothane was again attempted, and ventricular fibrillation developed. After defibrillation with 50 watt seconds of direct current, the arrhythmia reverted to junctional tachycardia. The patient has had no further surgical procedures. When seen at age 8 months, his rhythm was unchanged; he was asymptomatic and growing normally.

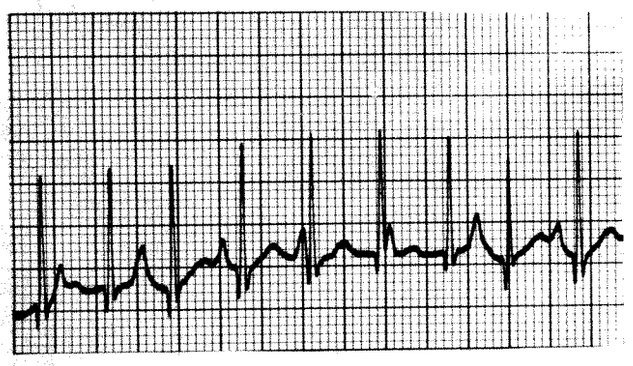

FIGURE 1. Lead II electrocardiogram obtained at age 7 months.

Although this patient's junctional tachycardia appeared to be benign, a dangerous arrhythmia developed under the stress of general anesthesia. I recommend premedication with propranolol and insertion of a temporary pacemaker before induction of general anesthesia in similar patients.

REPLY

Supraventricular tachycardias due to an ectopic focus are highly sensitive to sympathetic tone.[1] Pearl's patient demonstrated that during endotracheal intubation when sympathetic tone would most likely be high, either the junctional rate increased to 240/min with ventricular aberration or ventricular tachycardia developed. It would be impossible to distinguish between these two entities in the surface electrocardiogram, because each would have a prolonged QRS duration, with atrioventricular dissociation and possible fusion or capture beats. Halothane anesthesia is known to increase myocardial sensitivity to catecholamines and to decrease peripheral vascular resistance.[2] Ventricular fibrillation most likely developed because of the increase in sympathetic tone and increased sensitivity to catecholamines.

In managing Pearl's patient, we would further increase the propranolol dosage (up to 15 mg/kg daily). This dosage is usually well tolerated in children.[3] Our goal in therapy is to keep the heart rate in all patients at less than 150 beats/min. The development of cardiomyopathy in patients with chronic supraventricular tachycardia appears to be associated with more rapid heart rates.[1] We would have used an energy dose for defibrillation approximately one third of that used by Pearl. Assuming that a 3 month old infant weighs 4.5 to 5.4 kg, we would have used 10 to 12 joules for defibrillation. Gutgesell et al.[4] have established that the energy dose required for defibrillation in children is approximately 1 joule per pound. Since our report, we have had experience with three other patients, two of whom demonstrated the effects of increased sympathetic tone on junctional ectopic tachycardia. In the first patient, junctional ectopic tachycardia was noted soon after birth, and by age 8 months, although there was no other cardiac defect, the infant had chronic congestive heart failure. The rate of tachycardia was continuously higher than 250/min despite treatment with digoxin (0.01 mg/kg daily) and propranolol (18 mg/kg daily). On separate days, intravenous

phenytoin (15 mg/kg over 1 hour) and intravenous verapamil (0.15 mg/kg over 10 minutes) were given. Each resulted in a decrease in blood pressure and an *increase* in the rate of tachycardia. This was most likely due to a reflex increase in sympathetic tone caused by the hypotension. One week later, when the infant was undergoing endotracheal intubation for surgical ablation of the bundle of His and was anesthetized with halothane, ventricular fibrillation developed. After defibrillation, the bundle of His was successfully ablated by freezing, and a permanent ventricular pacemaker was implanted. The infant has been without junctional ectopic tachycardia for 3 months. He has entirely paced rhythm at a rate of 90/min.

The other patient, one of twins born with junctional ectopic tachycardia, also had mild hypotension in response to intravenous verapamil and had an increase in the rate of junctional ectopic tachycardia. The increased rate was reversed with intravenous calcium chloride, but the junctional tachycardia continued.

Therefore it appears that any agent that lowers blood pressure through either a decrease in systemic vascular resistance or a decrease in myocardial contractility may increase circulating catecholamines and increase the rate of junctional ectopic tachycardia. It is possible that phenylephrine with its attendant increase in vagal tone or calcium with its resultant increase in myocardial contractility might be successful acute treatment for junctional ectopic tachycardia in these situations.

We agree with Pearl that all patients with junctional ectopic tachycardia should receive propranolol before undergoing any surgical procedure. We would add that if the operation is elective, the patient should have a propranolol serum concentration greater than 40 ng/ml. A pacing catheter is not required for these patients. Bradycardia is unlikely and ventricular fibrillation will not respond to pacing. If the operation is performed as an emergency and the patient has not been receiving propranolol therapy, a pacing catheter should be inserted in the ventricle in case bradycardia develops, and propranolol, 0.1 mg/kg intravenously, should be given in four divided doses over 20 minutes before induction of anesthesia.

ABSENT RIGHT SUPERIOR VENA CAVA

Lenox et al.[1] attempted a review of all published cases of absent right superior vena cava; however, they overlooked the two cases reported by Marin-Garcia et al.[2] Both cases were recognized before operation (correction of coarctation of aorta in one and closure of an atrial septal defect under cardiopulmonary bypass in the other). Although Lenox et al. comment on certain problems that this anomaly may pose during cardiac surgery, it is important to emphasize those situations where the diagnosis of absent right superior vena cava is mandatory: for instance, when an associated cardiac defect has to be repaired using cardiopulmonary bypass. In this situation, in addition to cannulation of the inferior vena cava, cannulation of the left superior vena cava is necessary, which can be accomplished by way of the coronary sinus, which is usually very dilated. A Glenn procedure may be indicated in patients with cyanotic congenital heart disease and decreased pulmonary blood flow. In this situation absence of the right superior vena cava requires that anastomosis be carried out in the left side. When a Mustard procedure is indicated in patients with transposition of the great arteries, attachment of the interatrial baffle might be different if the right superior vena cava is absent. As Lenox et al. point out, this anomaly may be less rare than previously thought. The diagnosis can be accomplished by means of cardiac catheterization and angiocardiography.

REPLY

I apologize for omission of the two cases of absent right superior vena cava reported by Marin-Garcia et al.

In our review we did emphasize the importance of diagnosing absent right superior vena cava, both because of problems with cannulation at the time of surgery and because of the increased likelihood of conduction system abnormalities in the older patient with this entity. In cyanotic as well as noncyanotic heart disease, it is important to identify the presence of the right superior vena cava as well as persistent left superior vena cava. However, if augmentation of the blood supply to the pulmonary artery is needed, a Glenn procedure is rarely indicated.

In patients with transposition of the great arteries undergoing a Mustard procedure, the left superior vena cava would have to be cannulated. In cannulation of the left superior vena cava I again referred to Bosher,[1] who suggested that the cannula be advanced up the cava until its tip lies just inside the pericardium, thus decreasing the possibility of trauma to the conduction tissue in the area of the large coronary sinus. In performing the Mustard operation it is necessary to divert the large coronary sinus flow to the left-sided atrium and ventricle. This should be done cautiously because the conduction tissue extending from the atrioventricular node around the coronary sinus would be vulnerable to trauma.

I take this opportunity to add the case of unilateral left superior vena cava described by Holmes,[2] which was on the original list of cases to be included and was inadvertently left out. With the addition of these three cases there are 71 known cases at the present time.

It is hoped that, in time, more people will report their series. We would like to make a plea for electrophysiologic evaluation at the time of cardiac catheterization or microscopic study of the conduction system on postmortem material. In a future publication we will be reporting on the pathologic studies of

the conduction system in our two postmortem cases (Cases 1 and 2).

NONINVASIVE MEASUREMENT OF VENTRICULAR PRESSURE—I

Since the recent publication of our paper[1] on noninvasive measurement of ventricular pressure throughout systole, we have discovered two important and relevant publications.[2,3] Using the Navier-Stokes equation, these authors developed an equation for deriving aortic blood velocity from a continuous recording of aortic pressure. In our paper, we derived pressure from a left ventricular volume-time curve obtained by nuclear techniques, using the basic equation:

$$dP/dt = \rho v \gamma$$

They derived the equation:

$$dP/dt = \rho c \gamma + acv.$$

(dP/dt is the first derivative of the pressure, ρ is density of blood, v and γ are velocity and acceleration of the ejected blood, c is the pulse wave velocity, a is a constant.) The major differences between their approach and ours are: (1) They did not assume, as we did, that the velocity of the pulse wave equals the velocity of the blood; and (2) they introduced the term, acv, that accounts for friction. Their data support the validity of their equation, as do our recent experimental data.

In three dogs we examined the relation between the left ventricular time-activity curve obtained with a camera computer system and the changes in aortic root pressure measured with a catheter. In each dog the chest was opened and a calibrated electromagnetic flowmeter was placed around the aortic root; and a pressure transducer was introduced into the carotid artery, and with fluoroscopy was placed as close to the aortic valve plane as possible. We waited 4 days for recovery from the thoracic surgery and stabilization of the baseline of the flow tracing. Gated equilibrium radioventriculography with the dog in a 40° to 50° left anterior oblique position was performed together with pressure and flow recordings on an oscilloscope, at rest and under pharmacologic changes induced by dibenzylline or propranolol. Each dog received 15 mCi of technetium-99m human serum albumin intravenously. We obtained a left ventricular time-activity curve integrated over 6 minutes of acquisition. Ejection fraction (EF) was then calculated. A mean stroke volume (SV) was obtained from the flow tracing by analysis of 10 beats. The end-diastolic volume (EDV), calculated from the equation EDV = SV/EF, was used for calibration of the absolute volume-time curve. The area of the aortic opening was measured directly at postmortem examination. A calculated pressure tracing was derived using equation (5) of the publication. The pulse pressure ranged from 1 to 4 mm Hg in 12 experiments, instead of 20 to 40 mm Hg as recorded by the pressure transducer. These results can be interpreted as follows: Integration by parts of our equation gives the following result: $P - P_o = \frac{1}{2}\rho v^2$, which is the kinetic pressure. Kinetic pressure in the aorta had been measured and found to have values within a range similar to ours.[4]

Thus, we conclude that the shape of the ventricular pressure curve as a function of time can be derived from the ventricular volume-time curve throughout systole, but for calculation of absolute pressure, we also need a measurement of the pulse wave velocity. We are now exploring several approaches to the calculation of absolute pressure from the ventricular volume-time curve.

NONINVASIVE VENTRICULAR PRESSURE MEASUREMENTS—II

In attempting to measure ventricular pressure indirectly from the time-activity curve of ventricular ejection, Bourguignon and Wagner[1] have provided a new twist to an old controversy. In the first half of this century, a major goal of cardiovascular research was to do the opposite—to measure ventricular ejection from aortic pressure.[2] Attempts to do so proved unrewarding, because of the difficulty in characterizing arterial properties, and so identifying the separate components of cardiac ejection and vascular response in the arterial pressure pulse.

The method of Bourguignon and Wagner suffers from the same fundamental defect. Pressure generated in the ventricle during systole depends not only on the pattern of ventricular ejection but also on arterial viscoelasticity and blood density (which determine pulse wave velocity) and on the location of arterial branchings and terminations (which determine wave reflection). Studies of pressure and flow patterns and of vascular impedance in experimental animals and in man[3,4] have provided evidence of strong wave reflection, and of consequent augmentation in arterial and left ventricular pressure during systole. Thus, pressure in the ventricle during systole depends not only on the centrifugal wave generated by ventricular ejection but also on the centripetal waves that result from wave reflection.

No allowance is made for wave reflection in the calculations of Bourguignon and Wagner, which are based on the premise (their principle 2) that force, and so pressure, in the aorta are generated solely by acceleration of blood into the aorta.

In view of this fundamental deficiency, it is difficult to foresee the method described as having any more value than the older techniques that attempted the converse—measurement of ventricular ejection from arterial pressure.

REPLY

Our overall goal has been to measure both ventricular volume and pressure as a function of time, since this would make it possible to monitor ventricular work. As MacDonald[1] has stated, measurement of pulsatile flow can make as great a contribution to understanding of the physiology of the circulation as has measurement of pulsatile pressure. As he stated: "The creation of a flow of blood and its transport to and from the tissues is, after all, the purpose of the cardiovascular system. The accompanying pressure changes, although intimately related to the flow, are essentially of secondary interest." The greatest potential of nuclear techniques in cardiology is that for the first time they permit continuous monitoring of ventricular volume. On theoretical grounds it should be possible to derive the pressure pulse wave during systole from the ventricular volume-time curve, the velocity of the pulse wave at the opening of the aortic valve, and blood density. In 1956, Fry et al.[2] used a double lumen pressure transducer to measure the pressure pulse curve at two points in the ascending aorta. Starting with the Navier-Stokes equation, a general equation for hydrodynamic flow, they derived the equation $\Delta P/\Delta x = \rho\gamma + av$ (1), where $\Delta P/\Delta x$ is the pressure gradient between the two catheter openings; Δx, the distance between the openings; ρ, the blood density; γ, the acceleration of blood; a, a constant; and v, the blood velocity through the aorta. Fry et al. measured $\Delta P/\Delta x$, assumed ρ = 1.05 g/cm^3, obtained the value of a by assuming that flow was zero at the end of systole; and by integration of equation (1), he was able to derive v, the velocity of blood. In the same year Jones et al.[3] modified the method of Fry et al. so that a single lumen rather than a double lumen catheter could be used. Equation (1) of Fry et al. was modified by Jones et al. as follows: $dP/dt = \rho c\gamma + acv$ (2), where dP/dt is the first derivative of the pressure in the aorta; c, the velocity of the pulse wave; and the other terms as defined.

We have derived a similar equation using a different set of assumptions: $dP/dt = \rho c\gamma$ (3), where c is the pulse wave velocity; γ is the acceleration, the derivative of v, the velocity. We measure flow by nuclear techniques as the rate of emptying of the ventricle. Flow (F) is related to the velocity (v) of blood through the aortic valve opening by the equation: F = vA, where A is the area of the aortic valve opening.

O'Rourke is correct when he states that, in a sense, our goal is the opposite of that of others in the first half of this century in that we derive pressure from volume as they tried to derive flow from pressure. However, there are important differences in our theoretical as well as methodologic approaches. Where they used the pressure pulse contour technique, we use the ventricular volume curve and a new equation, related to that of Fry et al. and not to that of Remington and Hamilton to which O'Rourke refers. Remington and Hamilton used an aortic pressure pulse contour technique in which the pressure pulse contour was divided into intervals of 10 ms duration. This technique has not proved successful.

Our approach, being completely different from the pressure pulse contour method, does not suffer from the same problems. Our method describes the relation between pressure pulse, pulse wave velocity and blood velocity. Anything that changes one of the three variables alters the others according to equation (3).

A final point is that we do not question the existence of reflected waves, but many authors[4] have shown that these do not give detectable effects at the aortic opening.

At present we are trying various ways to measure the pulse wave velocity by nuclear techniques. If these are unsuccessful, we plan to combine the nuclear measurements of flow with Doppler measurements of blood velocity. MacDonald[1] showed that the mean blood velocity ($\bar{v}$), the velocity of the pulse wave (c), and the cross-sectional area (A) of the vessel are related together in the following equation $\bar{v}/c = \Delta A/A$. Knowledge of blood velocity (Doppler) and flow (nuclear techniques) would make possible the calculation of the velocity of the pulse wave.

SITE AND FREQUENCY OF INFECTION IN PORCINE VALVE BIOPROSTHESES

Ferrans et al.[1] presented ultrastructural observations in four infected bioprosthetic valves removed 6 days to 28 months after implantation; the thin layer of fibrin demonstrated on the bioprosthetic cusps was predicted to be material of high infective potential. The glutaraldehyde-stabilized porcine valve heterografts are certainly denuded of endothelium after fixation and, when implanted, are naturally covered with a thin layer of fibrin.

Clinical observations do not agree with this microscopic finding. In our own low profile bioprosthesis series (293 cases: mitral valve replacement, 114; aortic valve replacement, 83; double valve replacement, 26; valve replacement + associated procedures, 40), there were 4 cases of prosthetic endocarditis (incidence 4 of 293; 1.3 percent) in the follow-up period between 1976 and 1979. Of the four patients, two died after mitral and aortic valve replacement, respectively, and two recovered after aortic valve replacement.[2,3] In contrast, in our series with the Björk-Shiley prosthesis (220 cases: mitral valve replacement, 108; aortic valve replacement, 112) the incidence rate of prosthetic endocarditis was 5 percent after aortic valve replacement, and 2.68 percent after mitral valve replacement in the 5 year follow-up period from 1971 to 1976.

The small incidence of bioprosthetic endocarditis in the low profile bioprosthesis series may be due to the intensive search for chronic sepsis foci (specially oral and urinary) before surgery. Preparation of the patients for valve replacement is carried out by our Cardiological Department. In addition, intensive postoperative treatment with a wide spectrum of

antibiotic agents is provided for about 8 days in patients who have received a prosthetic cardiac valve.

REPLY

Navia and Liotta raise two separate, independent questions: the site of localization of infection in porcine valve bioprostheses and the frequency with which such infections occur. Our conclusion that infection in porcine bioprostheses is initially localized in the cusps is in agreement with the findings of Rossiter et al.[1] in a larger series of patients. Our suggestion that the fibrin layer covering the cusps of the bioprosthesis is the initial site of bacterial attachment is in agreement with observations made on animals with experimentally induced bacterial endocarditis,[2] in which interaction between bacteria and fibrin deposits in leaflets of natural valves (denudation of valve endothelium by trauma leads to formation of these fibrin deposits) has clearly been demonstrated. We have not stated that the layer of fibrin is material of "high infective potential" and we find no justification for the statement by Navia and Liotta that "Clinical observations do not agree with this microscopic finding."

No conclusions as to the actual incidence of infection of bioprostheses could be derived from our small series of patients; however, our paper's review of the several published series reveals an average incidence rate of 1.4 percent, which is similar to the rate of 1.3 percent reported by Navia and Liotta. More recently, other investigators have reported overall rates of infection of 1.7,[3] 0.88[4] and 0.85 percent in patients followed up for less than 1 year and 1.3 percent in patients followed up for more than 1 year.[5] The data presented by these investigators has not been expressed either in terms of patient-year linearized rates or in terms of early (less than 2 months) or late (more than 2 months) infection. Because of this, the differences in incidence of infection in these series of patients and in the patients with Björk-Shiley and porcine bioprostheses described by Navia and Liotta are difficult to evaluate. Rossiter et al.[1] reported a significantly greater ($p < 0.05$) incidence of early infection in bioprostheses (6 of 16 valves) than in Starr-Edwards prostheses (3 of 35 valves), but found a comparable overall (early plus late) rate of infection, and of mortality associated with infection, for these two types of prosthetic valves. All early infections in bioprostheses occurred in valves implanted in the aortic position. Rossiter et al.[1] reported linearized rates of infection of 2.2 percent and 0.1 percent for bioprostheses implanted in the aortic and the mitral position, respectively. The linearized rates of infection reported by Angell[6] in Angell-Shiley bioprostheses were 0.5 percent for patients with a mitral bioprosthesis, 0.5 percent for patients with an aortic bioprosthesis and 4.4 percent for patients with multiple bioprostheses. Magilligan et al.[7] considered porcine valve bioprostheses and mechanical valves to be equally resistant to infection.

Although the discrepancies between the linearized rates just cited for patients undergoing single valve replacement by a porcine bioprosthesis are relatively minor, it should be pointed out that the rates of infection in prosthetic cardiac valves depend on numerous factors in addition to the careful preoperative eradication of foci of infection. For example, narcotic addiction was considered a factor contributing to infection of the porcine valve bioprostheses in 4 of the 11 patients reported on by Magilligan et al.[7] and in 1 of the 4 patients described in our study.

CALENDAR OF EXTRAMURAL PROGRAMS

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the Continuing Education Committee for Extramural Programs assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The Continuing Education Committee for Extramural Programs of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

30th ANNUAL SCIENTIFIC SESSION
AMERICAN COLLEGE OF CARDIOLOGY

San Francisco, California **March 15–19, 1981**

- **Technical Exhibits**
  Deadline for requests for space: October 6, 1980
- **Scientific Exhibits**
  Deadline for requests for space: October 6, 1980
- **Young Investigators' Awards Competition**
  Entries must be postmarked no later than November 3, 1980

For application forms, write Sara Elliott, Director, Annual Scientific Session Department, American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

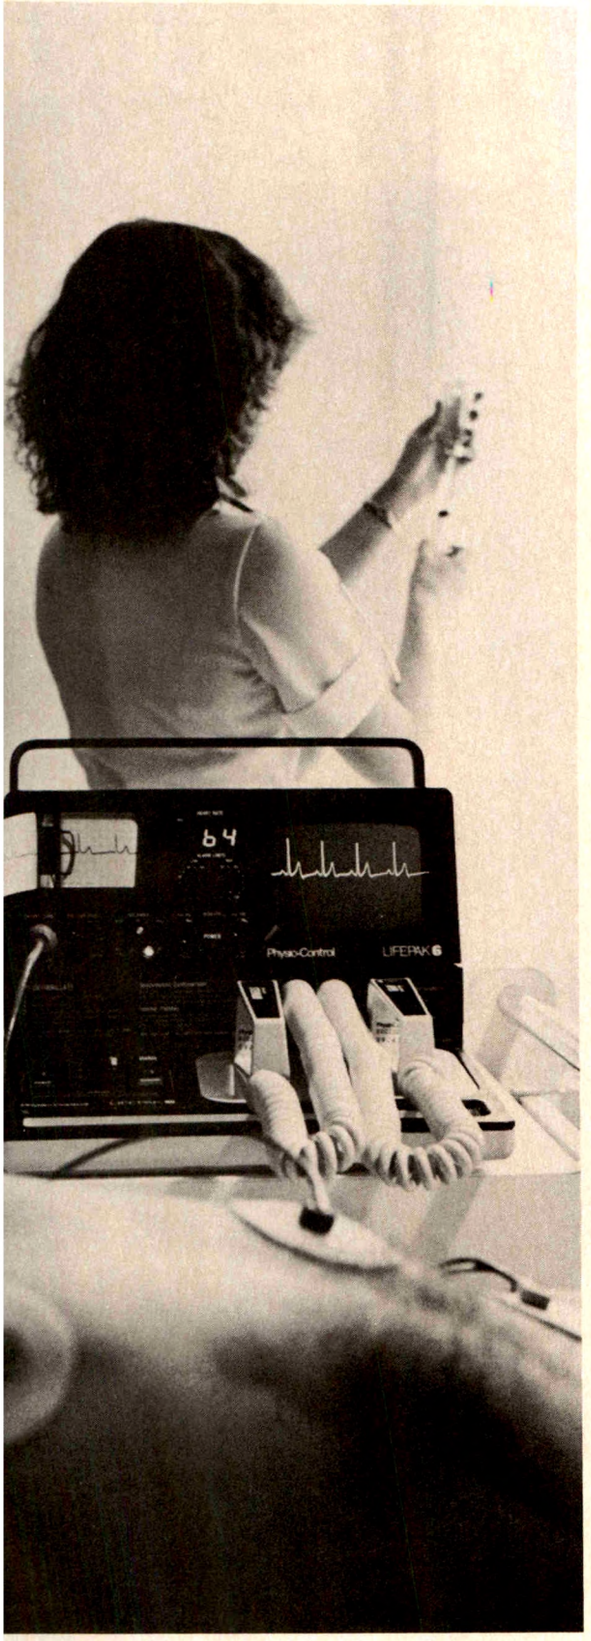
AMERICAN COLLEGE OF CARDIOLOGY

Announces . . .

AFFILIATE IN TRAINING MEMBERSHIP

For Physicians in Cardiovascular Related Training Programs

Candidates for this membership category must be current full-time trainees in a recognized cardiovascular (adult, pediatric, surgical) related program in fulfillment of requirements for admission to a subspecialty board examination which holds membership in the American Board of Medical Specialties. Upon completion of training and in order to maintain an affiliation with the College, the members are encouraged to apply to the Credentials Committee for status as an Associate Fellow or regular Affiliate.



The application for Affiliate in Training must be signed by the Director of the applicant's training program and two sponsors, both of whom must be Fellows of the College. One of the sponsors may be the Director of the training program, provided he is a Fellow of the College. The annual dues for an Affiliate in Training are $25.00.

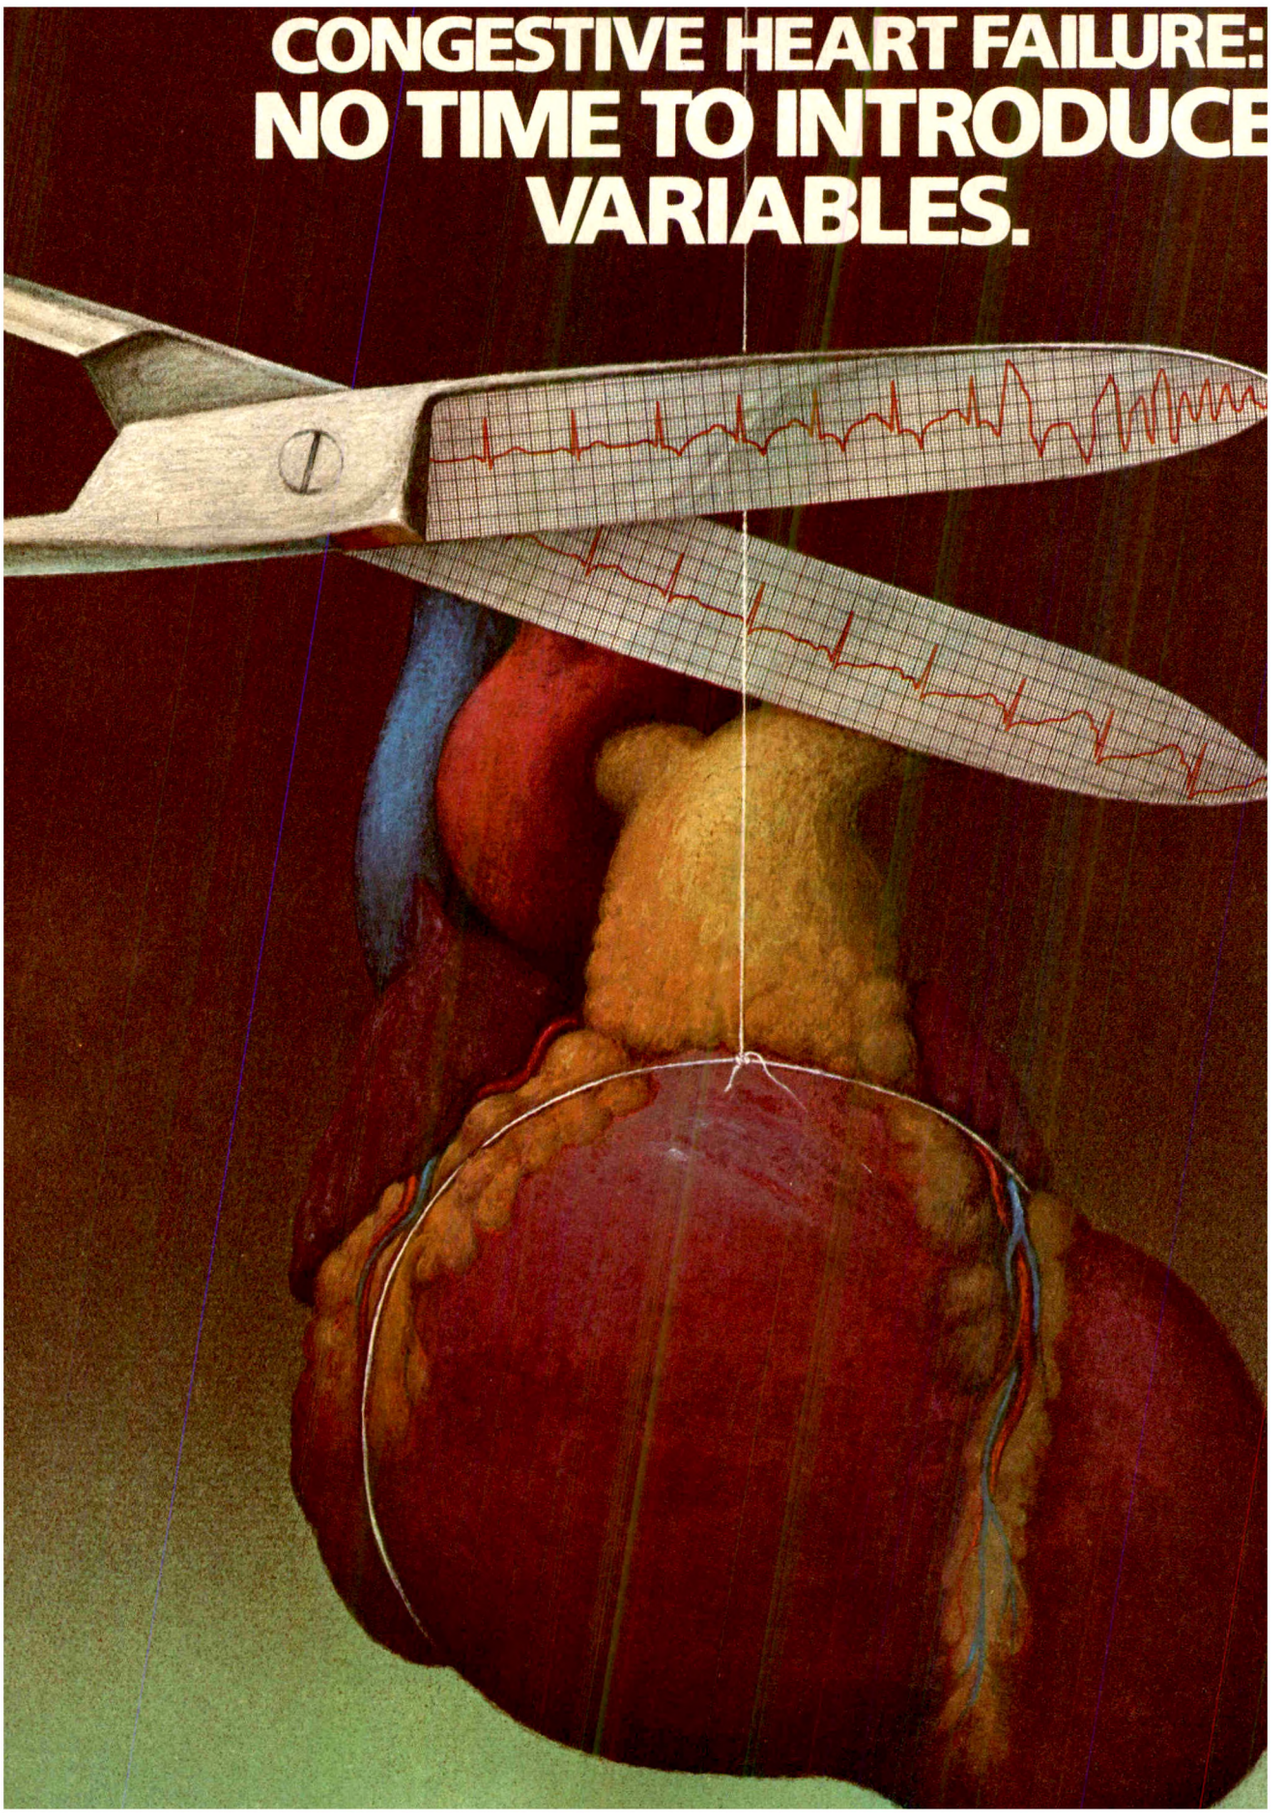
Advantages to the Affiliate in Training

1. Subscription to *The American Journal of Cardiology,* the official journal of the College.
2. Reduced fees for all educational programs of the College.
3. Preference for enrollment in programs sponsored by the College with a limited registration.
4. Receipt of the quarterly publication, *Cardiology,* the newsletter of the College.
5. Participation in all affairs of the College as a member rather than as a guest of the College.

Those desiring an application form should write to Director, Membership Department, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

How to keep a close watch with your back turned.

Machines don't save lives, people do. And our Lifepak® 6 defibrillator/monitor is conceived and built with one goal in mind—to help *you* deal successfully with critical cardiac emergency.



It functions as your partner. It watches constantly, unblinkingly. It feeds you information visibly on the digital rate meter, on the scope and on the recorder. It audibly tells you what's happening through the QRS beeper and high and low rate alarms. If there's trouble—fibrillation—you hear about it the moment it happens. And the Lifepak 6 is ready to help you deal with it. Large, color-coded function buttons. Clear instructions. Simple controls.

You see, no other company in the world has had more experience with emergency defibrillation. And being as close to the field as we are, we have the keenest possible appreciation for the situation in which our devices are employed. Machines don't save lives, people do. And people dealing with cardiac emergencies need all the help they can get. That's why the design of our machines, the engineering of our machines, and the servicing of our machines is absolutely the finest. Count on it.

Only **Physio-Control** makes the Lifepak.®

Physio-Control is the world leader in acute cardiac care systems. 11811 Willows Road, Redmond, Washington 98052 (206) 881-4000/U.S. Telex: 320268, International Telex: 320166. Lifepak and Physio-Control are registered trademarks.

CONGESTIVE HEART FAILURE:
NO TIME TO INTRODUCE
VARIABLES.

If you wouldn't think of changing your brand of digitalis, shouldn't you think twice before switching from LASIX® furosemide to a substitute?

BRAND OF

Both digitalis and diuretics are almost always used in congestive heart failure. But both can cause serious cardiac arrhythmias.[1] Digitalis, because digitalization is one of the most precarious titrations in all of medicine. And diuretics, because diuretic-induced hypokalemia increases the vulnerability to digitalis toxicity.[2] See warnings and precautions in the brief summary of product information on the next page.

In serious congestive heart failure, the diuretic most frequently administered with digitalis is LASIX® brand of furosemide. However, the bioavailability of furosemide may be significantly altered by a change in tablet disintegrants and/or excipients.[3,4,5] And variations in the bioavailability of unlawfully-marketed furosemide tablets have produced unpredictable and serious clinical effects.[6]

Therefore, once the patient is stabilized on digitalis and LASIX®, changes in his cardiac regimen should be minimized.

LASIX®—the diuretic with the best record of success in all degrees of congestive heart failure.

LASIX® is the original brand of furosemide. It is LASIX® that established the standard for furosemide performance. It is LASIX® that is the subject of almost 6,000 published papers. It is LASIX® that has been used successfully in millions of digitalized patients over the past 14 years. And it is LASIX® that has a remarkable quality-control record—almost 8 billion tablets manufactured without a single product recall.

LASIX® tablets are available in a dosage strength to meet almost every patient need—20, 40 and 80 mg.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

IN CONGESTIVE HEART FAILURE.

LASIX®
FUROSEMIDE

ONE LESS VARIABLE IN THE DIGITALIZED PATIENT

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide). Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Because animal reproductive studies have shown that furosemide may cause fetal abnormalities, the drug is contraindicated in women of childbearing potential. Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter; and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use.

It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

A Guide to Cardiac Dysrhythmias in Children

By ARTHUR GARSON, JR., M.D., PAUL C. GILLETTE, M.D., and DAN G. McNAMARA, M.D.

A Clinical Cardiology Monograph

FROM THE PREFACE: This guide contains the most common disturbances of heart rate, rhythm, and impulse conduction in children. It is intended to serve as a quick reference to specific dysrhythmias rather than as a complete textbook of pediatric electrocardiography.

SECTION HEADINGS: Systematic Interpretation of Cardiac Dysrhythmias in Children. Sinus Rhythm. Disturbances of Cardiac Rate and Rhythm. Disturbances of Cardiac Conduction. Artificial Pacemakers.

1980, 208 pp., 100 illus., $19.50 ISBN: 0-8089-1261-5 7915-20

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 15th Edition

Arthur J. Lewis, MD, Editor
Gertrude Dittus Gonzales, R.Ph., B.S., Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 15th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main secton as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

And, our Free Updating Service informs you of changes in specifications and introduces new drugs. These periodic supplements adopt the same easy-to-read format of the basic volume. You receive them free of charge until the publication of the next (16th) Edition.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

Yorke Medical Books
666 FIFTH AVENUE

KATO®
(potassium chloride for oral solution)

20 mEq (1.5 g. KCl)

Prescribing Information

DESCRIPTION:
Spray-dried tomato powder containing 20 mEq potassium (equivalent to 1.5 g. KCl) per 6 grams powder (one dose) with natural and synthetic flavors, spices and colors. Benzoic acid and potassium benzoate added as preservatives. When reconstituted as directed, makes a pleasantly flavored, low sodium tomato juice drink. Each daily dose (2 packets) contains less than 10 mg. sodium.

INDICATIONS:
The prevention or correction of potassium deficit, particularly when accompanied by hypochloremic alkalosis in conjunction with thiazide diuretic therapy, in digitalis intoxication, or as the result of long-term corticosteroid therapy, low dietary intake of potassium, or excessive vomiting or diarrhea.

CONTRAINDICATIONS:
Potassium is contraindicated in severe renal impairment involving oliguria, anuria or azotemia; in untreated Addison's disease, familial periodic paralysis, acute dehydration, heat cramps, hyperkalemia from any cause. Potassium chloride should not be employed in patients receiving potassium-sparing agents such as aldosterone antagonists and triamterene.

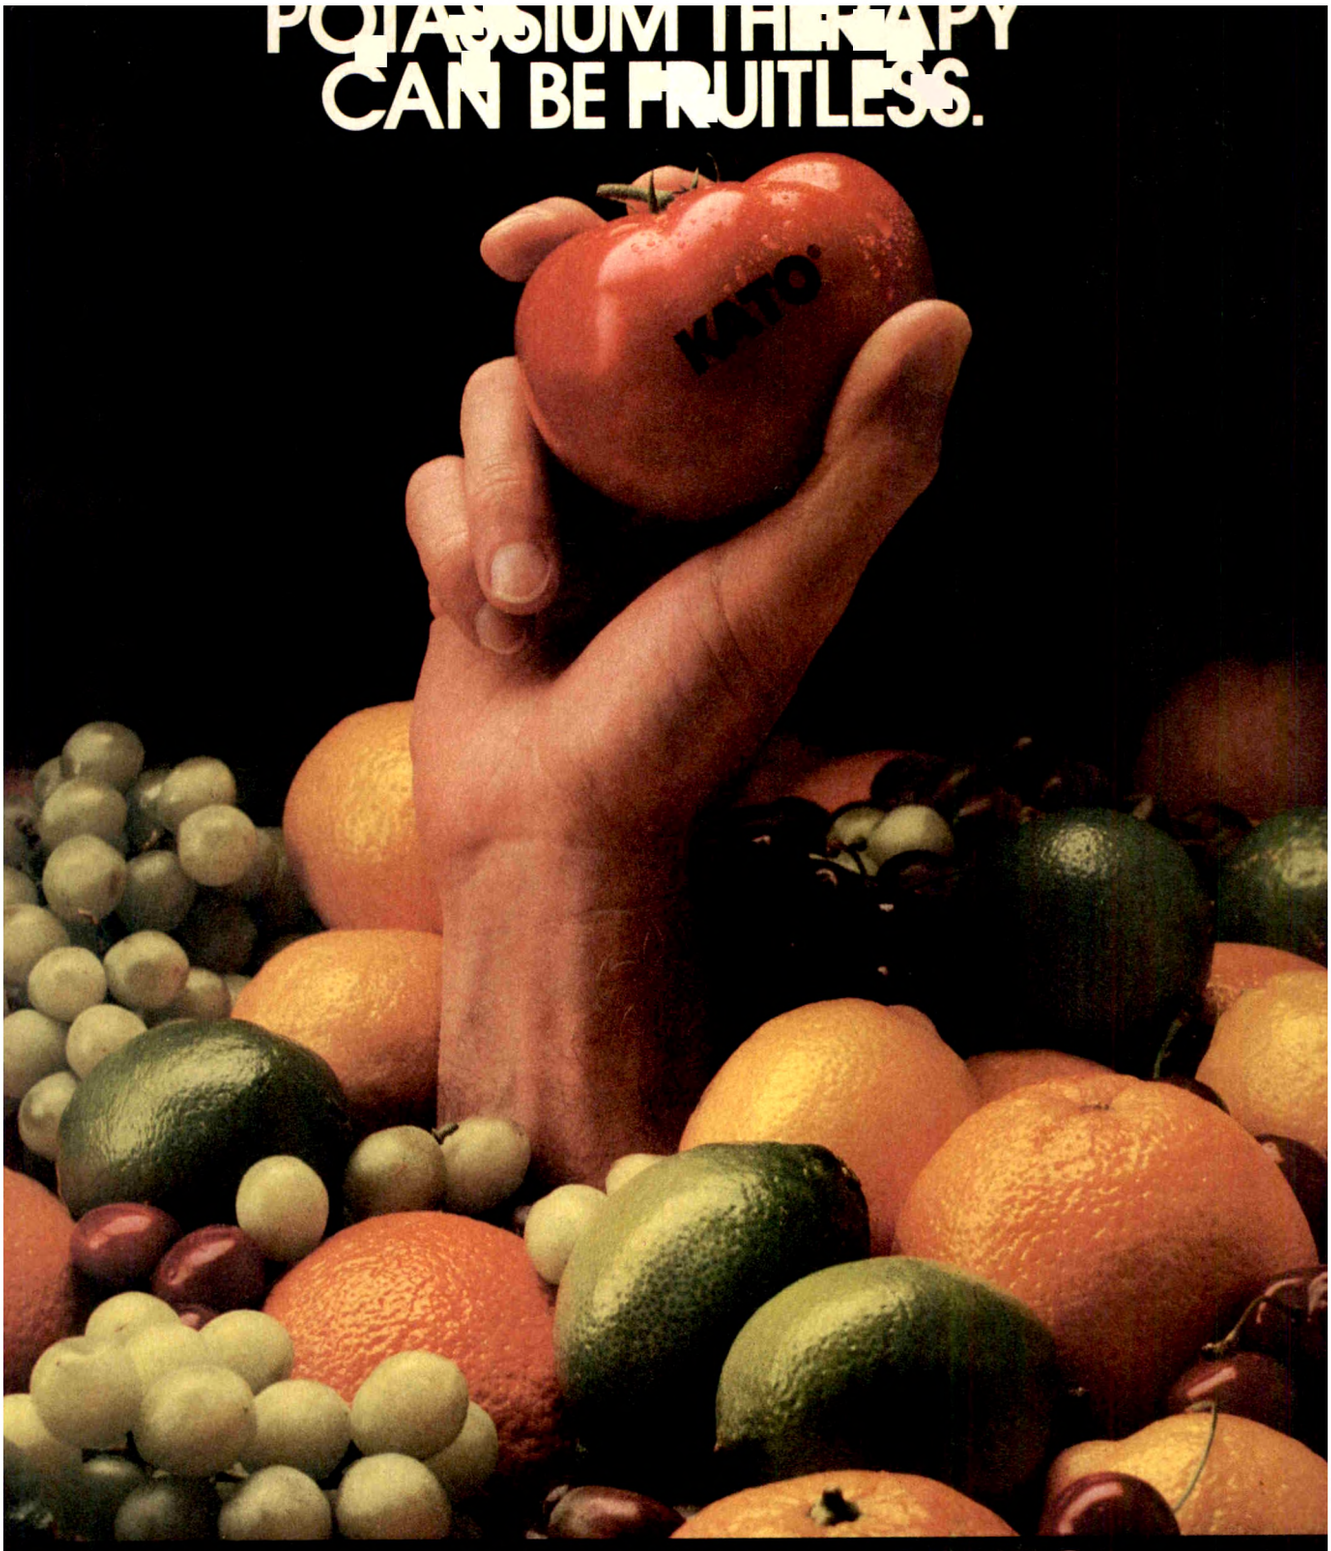
PRECAUTIONS:
KATO is a concentrate and should be taken only after reconstituting with water as directed. This preparation, like other potassium supplements, must be properly diluted to avoid the possibility of gastrointestinal irritation. Do not use in patients with low urinary output or renal decompensation. Administer with caution; it is impossible to assess accurately the daily dose required. Excessive dosage may result in potassium intoxication. Frequent checks of the clinical status of the patient, ECG and/or plasma potassium level should be made. High plasma concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease.

ADVERSE REACTIONS:
Vomiting, diarrhea, nausea, and abdominal discomfort may occur. Gross overdosage may produce signs and symptoms of potassium intoxication: mental confusion, listlessness, paresthesia of the extremities, weakness and heaviness of legs, flaccid paralysis, hyperkalemia, ECG abnormalities, fall in blood pressure, cardiac arrhythmias and heart block. The characteristic changes in the ECG are disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, tall peaked T waves, etc.

TOXICITY:
Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

TREATMENT OF HYPERKALEMIA:
1. Dextrose solution 10% or 25% containing 10 units of crystalline insulin per 20 g. dextrose, given I.V. in a dose of 300cc to 500cc in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally or as retention enema. 3. Hemodialysis or peritoneal dialysis. 4. Elimination of potassium-containing foods and medicaments. Warning: Digitalis toxicity can be precipitated by lowering the plasma potassium concentration too rapidly in digitalized patients.

ADMINISTRATION AND DOSAGE:
Mix with water to make a pleasant tomato juice drink. Each 6 gram unit dose packet provides 20 mEq of potassium. Usual adult dose—1 packet of KATO mixed with about 2 ounces of water twice daily—supplies 40 mEq potassium per day. Take with meals or follow with ½ glass of water. Larger doses may be required, but should be administered under close supervision because of the possibility of potassium intoxication.



HOW SUPPLIED:
Cartons of 30 and 120 6 gram unit dose packets, 20 mEq each.

02-488-30
1-79

SYNTEX

SYNTEX PUERTO RICO, INC.
HUMACAO, PUERTO RICO 00661

POTASSIUM THERAPY CAN BE FRUITLESS.

Trying to smother the taste of potassium with sweet fruit flavorings never seems to work very well. It's like pouring salt straight into your orange juice—and just about as undrinkable for many patients. That's when a matter of taste becomes a problem of compliance.

KATO® (potassium chloride for oral solution) has the right kind of taste, the fresh tomato tang that naturally complements the saltiness of potassium chloride.

It provides the potassium salt of choice—the chloride—as a powder that mixes quickly with water, for the liquid dosage form preferred for safety. Each easy-to-use packet contains 20 mEq potassium chloride, with less than 5 mg sodium.

Offer your patients the tangy taste of KATO—the fruitless supplement for fruitful therapy.

KATO®
(potassium chloride for oral solution) 20 mEq (1.5 g. KCl)
Potassium with the tang of tomato.

Now in book form... the latest **Update Your Medicine** lectures

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

CORNELL MEDICAL UPDATE/2

Edited by LILA A. WALLIS, MD, FACP

Each of the 23 lectures is presented in a workbook format for easy reading and quick comprehension.

1. Cardiology, I: Applications of Anticoagulation; Coronary Artery Bypass Surgery; Valvular Heart Disease
2. Cardiology, II: Congenital Heart Disease in Adults, Part I
3. Cardiology, III: Congenital Heart Disease in Adults, Part II
4. Hematology: Hemostasis Made Easy
5. Gastroenterology, I: Cricoesophageal Achalasia and Gastroesophageal Reflux
6. Gastroenterology, II: Pharmacology of Acid Peptic Disease Therapy
7. Genetics, I: Basic Genetics
8. Genetics, II: Chromosomal Abnormalities
9. Genetics, III: Clinical Genetics
10. Gynecology, I: New Diagnostic Procedures and Therapy
11. Gynecology, II: New Diagnostic Procedures
12. Obstetrics: Prenatal Diagnosis of Genetic Diseases and Abnormalities
13. Infectious Diseases, I: Antimicrobial Therapy
14. Infectious Diseases, II: Virology
15. Nephrology, I: Renal Glomerular Disease
16. Nephrology: II: Management of Chronic Renal Failure
17. Ophthalmology, I: Progress in Ophthamology
18. Ophthalmology, II: Diabetic Retinopathy Vitrectomy Study
19. Psychopharmacology, I: Antipyschotic Drugs and Minor Tranquilizers
20. Psychopharmacology, II: Antidepressant Drugs
21. Pulmonary Medicine: Recent Advances
22. Rheumatology: Recent Advances
23. Calcium Metabolism: Disorders of Calcium Metabolism

All new material—specialties expanded.

The workbook format of CORNELL MEDICAL UPDATE/2 breaks medical publishing traditions by giving practitioners a quick overview of the latest advances in their specialty. It transcribes the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical Center. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice.

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 Fifth Avenue, New York, N.Y. 10103

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00 a copy. I may use the book for 30 days and if not completely satisfied, return it for full refund or credit.

LEA & FEBIGER

NEW! Will you just take a look at this list of books!

Plan now to examine our many new books at the American Heart Association meeting in Miami Beach, Florida, November 17–20, 1980. We will be at Booth C-27

ECHOCARDIOGRAPHY, 3rd ed.

By HARVEY FEIGENBAUM, M.D., *Indiana University School of Medicine, Indianapolis.* This book by Doctor Harvey Feigenbaum has been the principle authoritative book in the field since publication of the first edition. This new Third Edition maintains and improves on that status. It represents a definitive, thorough discussion of instrumentation, technical aspects of application, and future trends by a pioneer in the field. Major coverage of two-dimensional echocardiography is now featured in this third edition. Discussion of this relatively new technique represents a major part of the text and is the principle reason for the increase in size. *About 700 pp. (7 X 10), 732 illus. (2 in color), 1980, Ready Soon.*

CARDIAC CATHETERIZATION AND ANGIOGRAPHY, 2nd ed.

Edited and with contributions by WILLIAM GROSSMAN, M.D., *Peter Bent Brigham Hospital, Boston, Massachusetts. (24 Contributors).* This new edition provides an authoritative and completely up-to-date summary of the major techniques currently employed in cardiac catheterization and angiography. New chapters in this second edition discuss underlying principles for proper operation and utilization of radiologic and cineangiographic equipment, complications of cardiac catheterization, therapeutic uses of the catheter and special diagnostic techniques. Review of previous edition: "Magnificent." — *The American Journal of Cardiology. 427 pp. (7 X 10), illus., 1980, $34.50.*

PROGRESS IN CARDIOLOGY. 9

Edited by PAUL N. YU, M.D., *University of Rochester School of Medicine and Dentistry, Rochester, New York; and* JOHN F. GOODWIN, M.D., *Royal Postgraduate Medical School, London, England. (11 Contributors). Partial Contents:* Primary Prevention of Coronary Heart Disease: An Appraisal of Clinical Trials of Reducing Raised Plasma Cholesterol; Management of the Late Phase of Acute Myocardial Infarction; The Prevention and Treatment of Infective Endocarditis; Axial Tomography of the Heart; Variations in the Practice of Cardiology: Some Problems Encountered in India. *About 250 pp. (7 X 10), illus., 1980, Ready Soon.*

CARDIAC REHABILITATION, ADULT FITNESS AND EXERCISE TESTING

By PHILIP K. WILSON, Ed.D., *La Crosse Exercise Program, University of Wisconsin, La Crosse;* PAUL S. FARDY, Ph.D., *St. Catherine Hospital, East Chicago, Indiana; and* VICTOR F. FROELICHER, M.D., *University of California, San Diego.* A book that has been long-needed in the field, this text provides extensive coverage of all aspects of cardiac rehabilitation and adult fitness programs, with an additional emphasis placed upon the theory, procedures, and techniques of exercise testing. *About 400 pp., illus., 1980, Ready Soon.*

CARDIAC EMERGENCY CARE, 2nd ed.

Edited and with contributions by EDWARD K. CHUNG, M.D., *Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania. (22 Contributors).* Busy primary care physicians, house officers, critical care nurses and others will appreciate the new format and quick and easy access to information provided in this Second Edition. Three new chapters dealing with sick sinus syndrome and brady-tachyarrhythmia syndrome, nursing aspects of cardiac emergency care, and radiological diagnosis in cardiopulmonary emergenci are included. *475 pp., illus., tables, 19 $25.00.*

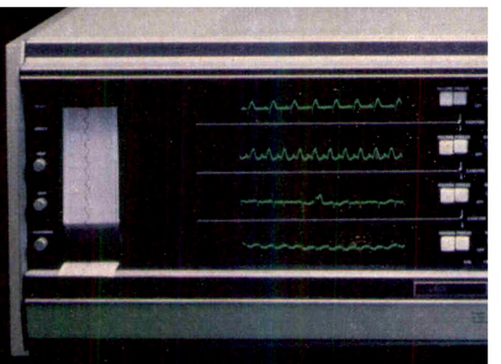
GUIDELINES FOR GRADED EXERCISE TESTING AND EXERCISE PRESCRIPTION, 2nd ed.

Edited by the AMERICAN COLLEGE C SPORTS MEDICINE, *Madison, Wiscons Prepared by the Task Force of the Po graduate Education Committee.* Wi particular attention to programs which a safe, well-organized, and philosophica sound, this new Second Edition sets for a rationale for the establishment of effe tive and efficient graded exercise testir exercise prescription, and exercise pr grams for asymptomatic subjects of ages, as well as patients with cardiovascu and respiratory disease. *151 pp., tabl paperback, 1980, Ready Soon.*

INTERPRETATION OF COMPLEX ARRHYTHMIAS

By ALFRED PICK, M.D., and RICHAR LANGENDORF, M.D., both of the Cardi vascular Institute of Michael Reese Hospi and Medical Center, and Pritzker School Medicine, The University of Chicago, C cago, Illinois. *586 pp. (11 X 8½), illus., 19 $58.50.*

CARDIAC PACING: A Concise Guide to Clinical Practice



Edited and with contributions by PHIL VARRIALE, M.D., and EMIL A. NACLERI M.D., both of Cabrini Medical Center, Ne York, New York. (34 Contributors). *382 p (7 X 10), illus., 1979, $27.50.*

CLINICAL CARDIAC ELECTROPHYSIOLOGY: Techniques and Interpretations

By MARK E. JOSEPHSON, M.D., Univers of Pennsylvania School of Medicine, Phi delphia; and STUART F. SEIDES, M.I George Washington University School Medicine, Washington, D.C. *318 pp. (7 10), numerous illus., 1979, $24.50.*

Becton Dickinson Announces A Quantum Leap Ahead in Computerized Arrhythmia Monitoring...

VIGILANT™

Introducing VIGILANT. State-of-the-art instrumentation so remarkably accurate in the recognition of complex cardiac events, it emerges as the first arrhythmia IDENTIFICATION system.

With its prompt detection of arrhythmias[1] and clinically proven accuracy[2], with its sophisticated arrhythmia recall capabilities, and its outstanding analytical features, VIGILANT takes arrhythmia classification beyond mere patient monitoring.

Utilizing advanced signal processing technology, this third-generation, multiparameter computer system has been clinically documented to have a beat detection accuracy of 99.94%[3]. And, since it has a proven false positive VPB rate of only 0.1% and false negative VPB rate of only 4.6%[4], VIGILANT provides an instant and reliable upgrade in CCU/ICU management.

Specifically, this expanded capability means accurate, on-line recognition of VPBs; reliable identification of dangerous arrhythmias; comprehensive data storage and retrieval facilities; quantitative drug response measurements; and a potential savings of time and money through the more efficient use of personnel[5].

If you've had doubts about the accuracy and effectiveness of computerized arrhythmia monitoring systems, take a look at the first computer-assisted arrhythmia IDENTIFICATION system. VIGILANT from B-D. It's a quantum leap ahead . . . for you, your staff and your patients!

The Pacekeeper™

For ventricular arrhythmias.
For atrial arrhythmias.
For smooth, trouble-free conversion.
For steady maintenance.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

- ☐ Greater GI tolerance than with quinidine sulfate
- ☐ Full quinidine cardiodynamics
- ☐ Convenient b.i.d. or t.i.d. dosage for most patients

CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of a broad range of cardiac arrhythmias (see Brief Summary). After conversion to normal sinus rhythm—whether with CARDIOQUIN Tablets or electroconversion—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required for maintenance in most cases. The polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., Krantz and Carr's Pharmacologic Principles of Medical Practice, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quini polygalacturonate) are indicated in the treatment of: premature a and ventricular contractions; paroxysmal atrial tachycardia; paro mal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillat established atrial fibrillation when therapy is appropriate; paroxys ventricular tachycardia when not associated with complete he block; maintenance therapy after electrical conversion of atrial fi lation and/or flutter. CONTRAINDICATIONS: Aberrant impulses abnormal rhythms due to escape mechanisms should not be trea with quinidine. WARNING: In the treatment of atrial flutter rever to sinus rhythm may be preceded by a progressive reduction in degree of AV block to a 1:1 ratio and resulting extremely rapid v tricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quini polygalacturonate 275 mg.) is equivalent in quinidine content grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dos must be adjusted to individual needs, both for conversion and m tenance. An initial dose of 1 to 3 tablets may be used to termi arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhy is not restored after 3 or 4 equal doses, the dose may be increa by ½ to 1 tablet (137.5 to 275 mg.) and administered three to times before any further dosage increase. For maintenance, tablet may be used two to three times a day; generally one ta morning and night will be adequate. SUPPLIED: Uncoated, sco tablets in bottles of 100.

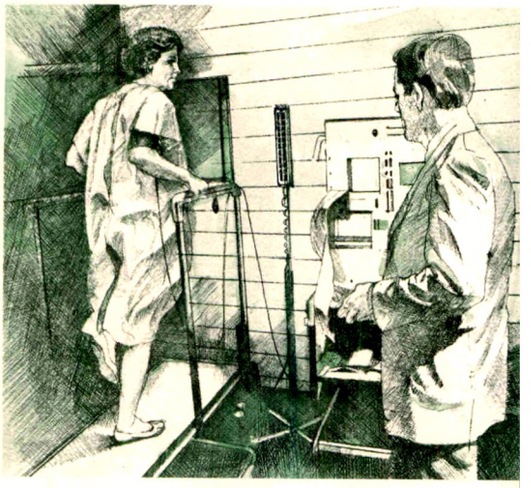
ANSWERS ABOUT ALDOMET® (METHYLDOPA|MSD)

Will an antihypertensive generally allow a normal cardiovascular response to exercise?

Cardiac output and blood pressure normally increase with increasing physical activity. ALDOMET does not significantly impair normal fluctuations of blood pressure during exercise.[1,2]



In a recent study of hypertensive patients whose cardiovascular response to exercise was evaluated before and during methyldopa therapy, "...methyldopa significantly reduced the rise in systolic pressure during the build-up ($P<0.01$) and subjective maximal stages ($P<0.05$) as well as at all phases of recovery ($P<0.01$)." Moreover, "The total duration of exercise (an index of work capacity) was unchanged with...methyldopa."[3]

Such findings can be of importance to active hypertensive patients such as the athletic individual or the person whose work requires substantial physical effort. For these and many other hypertensive patients, ALDOMET represents a logical therapeutic choice.

With ALDOMET, exercise hypotension rarely occurs. Sedation, usually transient, may occur during the initial period of therapy or whenever the dose is increased. Headache, asthenia, or weakness may be noted as early and transient symptoms.

ALDOMET® offers many (METHYLDOPA|MSD) other important features:

- Highly effective in all degrees of hypertension.
- Existing cardiac output is usually maintained.
- Renal blood flow is usually maintained.
- Has documented long-term efficacy.
- Significant adverse effects have been infrequent and the agent is usually well tolerated.

ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, and if previ methyldopa therapy has been associated with liv disorders. It is important to recognize that a posit Coombs test, hemolytic anemia, and liver disord may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorde could lead to potentially fatal complications unle properly recognized and managed.

MSD
MERCK SHARP & DOHME

For hypertension—

ALDOMET®
(METHYLDOPA|MSD)

The most prescribed nondiuretic antihypertensive in the U.S. today

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression.

Cardiovascular: Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.)

Gastrointestinal: Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis.

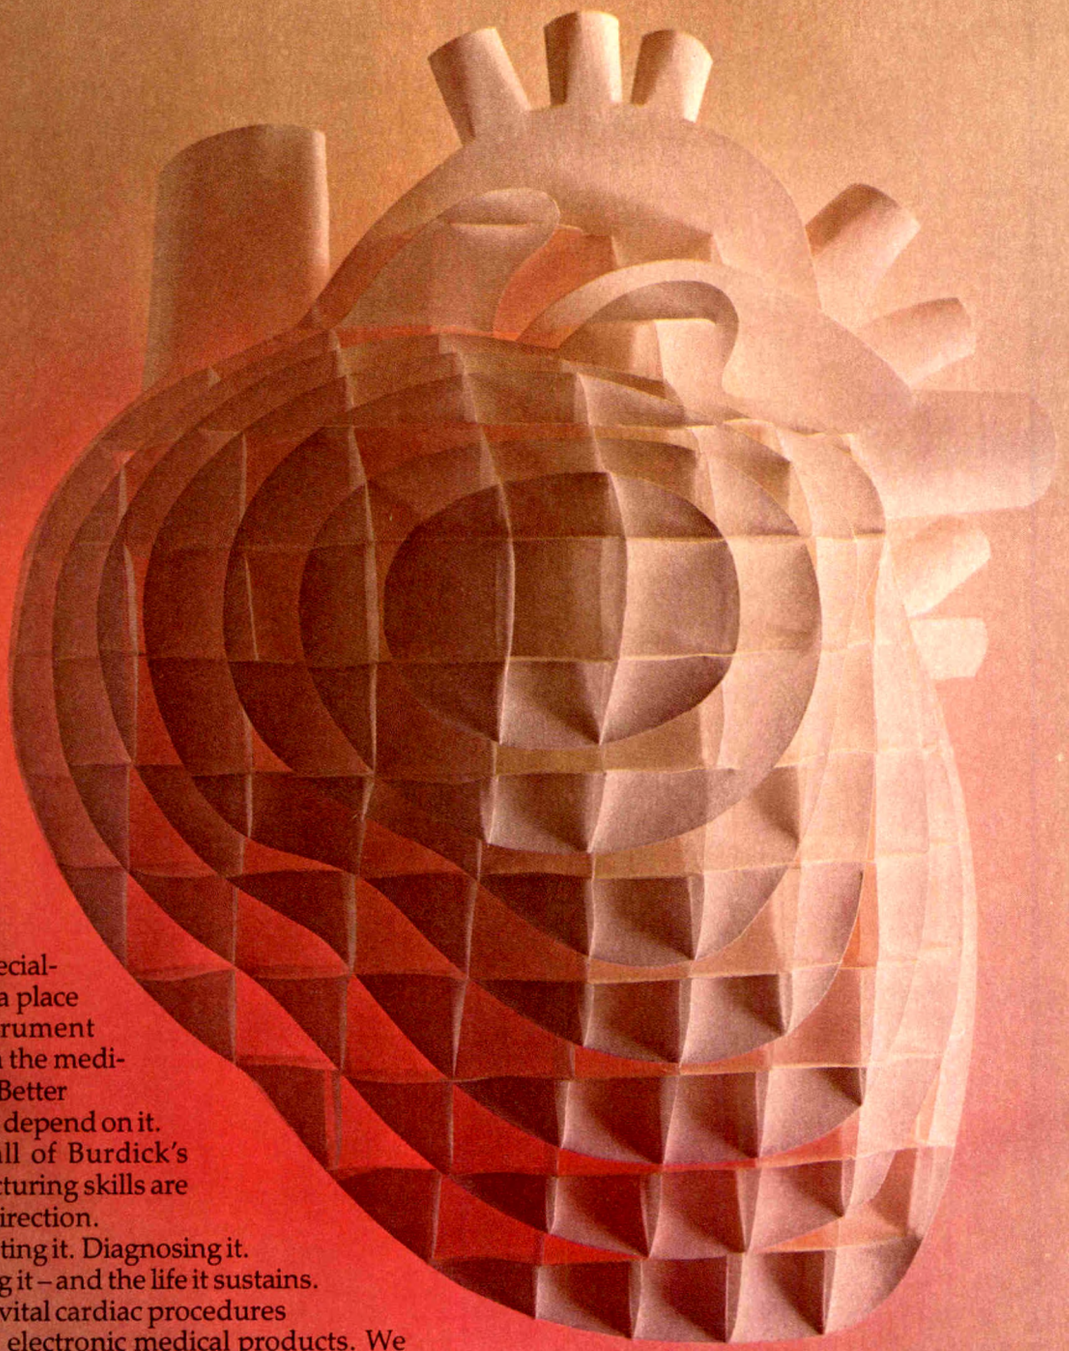
Hepatic: Abnormal liver function tests, jaundice, liver disorders.

Hematologic: Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor.

Allergic: Drug-related fever, lupus-like syndrome, myocarditis.

Other: Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.



How Supplied: Tablets, containing 125 mg methyldopa each, in bottles of 100; Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000; Tablets, containing 500 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 500.

JOAM34(709)

We give the heart our undivided attention. In many different ways.

We believe specialization has as much a place in the medical instrument industry as it does in the medical profession itself. Better health care products depend on it.

That's why all of Burdick's design and manufacturing skills are focused in a single direction.

The heart. Testing it. Diagnosing it. Monitoring it. Saving it – and the life it sustains.

Each of these vital cardiac procedures requires specialized electronic medical products. We proudly put the Burdick name on our single and multi-channel electrocardiographs. Cardiac monitors and defibrillators. Cardiac emergency systems. Ambulatory monitoring systems. Exercise tolerance systems – from basic office configurations to high-volume hospital systems. And more.

It adds up to a full range of reliable, cost-effective cardiology instruments. Each a part of our *concern for cardiac care*. Each a tangible expression of superior technology, quality workmanship, and a product development capability that is keenly aware of the ever-changing needs of the medical profession.

In Hypertension*...When You Need to Conserve K^+

Every Step of the Way

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

†Step 1 usually consists of an initial phase (a diuretic alone), a titration phase (dosage adjustment and/or addition of a K^+ supplement or K^+-sparing agent), and a maintenance phase (a diuretic alone or in combination with a K^+ supplement or K^+-sparing agent).

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F Co. literature or *PDR*. A brief summary follows:

* **WARNING**
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible bocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K^+ frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia, although uncommon, has been reported. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

CONTENTS IN BRIEF

CLINICAL STUDIES

721 **Calcific Deposits in Porcine Bioprostheses: Structure and Pathogenesis.** Victor J. Ferrans, Steven W. Boyce, Margaret E. Billingham, Michael Jones, Tokuhiro Ishihara and William C. Roberts

735 **Chronic Intravascular Hemolysis After Aortic Valve Replacement With Ionescu-Shiley Xenograft: Comparative Study With Bjork-Shiley Prosthesis.** Pedro R. Febres-Roman, Wilson C. Bourg, Richard A. Crone, Richard C. Davis, Jr. and Troy H. Williams

739 **Two Dimensional Echocardiographic Recognition of the Descending Thoracic Aorta: Value in Differentiating Pericardial From Pleural Effusions.** William S. Haaz, Gary S. Mintz, Morris N. Kotler, Wayne Parry and Bernard L. Segal

744 **Histologic and Ultrastructural Features of Normal Human Parietal Pericardium.** Tokuhiro Ishihara, Victor J. Ferrans, Michael Jones, Steven W. Boyce, Oichi Kananami and William C. Roberts

754 **True Left Ventricular Aneurysm and Healed Myocardial Infarction. Clinical and Necropsy Observations Including Quantification of Degrees of Coronary Arterial Narrowing.** Henry S. Cabin and William C. Roberts

764 **Response to Exercise Early After Uncomplicated Acute Myocardial Infarction in Patients Receiving No Medication: Long-Term Follow-Up.** Gerald M. Koppes, William Kruyer, Charles H. Beckmann and Frederic G. Jones

770 **Improvement in Ventricular Function During Exercise Studied With Radionuclide Ventriculography After Cardiac Rehabilitation.** David Jensen, J. Edwin Atwood, Victor Froelicher, M. Dan McKirnan, William Ashburn and John Ross Jr. with the technical assistance of Judy Sassone, Mary Lou Strong and Julie Froelicher

778 **Relation of Exercise-Induced Physiologic S-T Segment Depression to R Wave Amplitude in Normal Subjects.** Myron C. Gerson, Stephen N. Morris and Paul L. McHenry

EXPERIMENTAL STUDIES

783 **Continuous Fractionated Electrical Activity After Stimulation of the Ventricles During the Vulnerable Period: Evidence for Local Reentry.** David E. Euler and E. Neil Moore

792 **Electrophysiologic Effects of Disopyramide Phosphate on Reentrant Ventricular Arrhythmia in Conscious Dogs After Myocardial Infarction.** Eugene Patterson, John K. Gibson and Benedict R. Lucchesi

800 **The No Reflow Phenomenon: A Time-Limiting Factor for Reperfusion After Coronary Occlusion?** John R. Darsee and Robert A. Kloner

METHODS

807 **Methodologic Problems of Exercise Testing for Coronary Artery Disease: Groups, Analysis and Bias.** John T. Philbrick, Ralph I. Horwitz and Alvan R. Feinstein

813 **Peak Systolic Blood Pressure/End-Systolic Volume Ratio: Assessment at Rest and During Exercise in Normal Subjects and Patients With Coronary Heart Disease.** Robert Slutsky, Joel Karliner, Kenneth Gerber, Alexander Battler, Victor Froelicher, Gabriel Gregoratos, Kirk Peterson and William Ashburn

821 **Influence of Coronary Artery Disease on Pulmonary Uptake of Thallium-201.** John B. Bingham, Kenneth A. McKusick, H. William Strauss, Charles A. Boucher and Gerald M. Pohost with the technical assistance of Frederick A. Godley

827 **Effect of Selective Coronary Arteriography on Left Ventricular Volumes and Ejection Fraction in Man.** Lawrence Stern, Brian G. Firth, Gregory J. Dehmer, Stacey M. Johnson, Roy V. Markham, Samuel E. Lewis and L. David Hillis

832 **Semiautomated Method for Evaluation of Left Ventricular Regional Wall Motion in Coronary Artery Disease.** Sanford E. Warren, Valmik Bhargava, Walter V. R. Vieweg, George W. Dennish, Joseph S. Alpert and Arthur D. Hagan

837 **High Speed Rotating Scanner for Transesophageal Cross-Sectional Echocardiography.** Kohzoh Hisanaga, Asako Hisanaga, Norio Hibi, Kinya Nishimura and Tadashi Kambe

PEDIATRIC CARDIOLOGY

843 **Prognostic Significance of Arrhythmia in Tetralogy of Fallot After Intracardiac Repair.** Hans U. Wessel, Christian K. Bastanier, Milton H. Paul, Teresa E. Berry, Roger B. Cole and Alexander J. Muster

849 **Pulsed Doppler Echocardiographic Evaluation of the Cyanotic Newborn: Identification of the Pulmonary Artery in Transposition of the Great Arteries.** James Geoffrey Stevenson, Isamu Kawabori and Warren G. Guntheroth

REPORTS ON THERAPY

855 **Efficacy, Plasma Concentrations and Adverse Effects of A New Sustained Release Procainamide Preparation.** Elsa-Grace V. Giardina, Paul E. Fenster, J. Thomas Bigger, Jr., Michael Mayersohn, Donald Perrier and Frank I. Marcus

863 **Further Insights Into Digoxin-Quinidine Interaction: Lack of Correlation Between Serum Digoxin Concentration and Inotropic State of the Heart.** Paul D. Hirsh, Howard J. Weiner and Robert L. North

DIAGNOSTIC SHELF

869 **Differentiation of Left Ventricular Pseudoaneurysm From True Aneurysm With Two Dimensional Echocardiography.** Robert P. Gatewood, Jr. and Navin C. Nanda

879 **Gallium-67 Citrate Scanning for Noninvasive Detection of Inflammation in Pericardial Diseases.** John B. O'Connell, John A. Robinson, Robert E. Henkin and Rolf M. Gunnar

CASE REPORTS

885 **Congenital Hypoplasia of Portions of Both Right and Left Ventricular Myocardial Walls. Clinical and Necropsy Observations in Two Patients With Parchment Heart Syndrome.** Bruce F. Waller, Eldon R. Smith, Brian D. Blackbourne, Felix P. Arce, Nellie N. Sarkar and William C. Roberts

892 **Biventricular Hypoplasia With Myocardial Fiber Hypertrophy and Disarray.** William C. Little, H. Cecil Coghlan and Jack C. Geer

QUICK QUIZ

Fig. 1

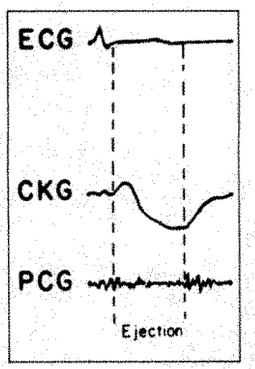

Fig. 2

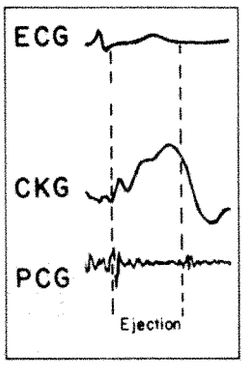

Fig. 3

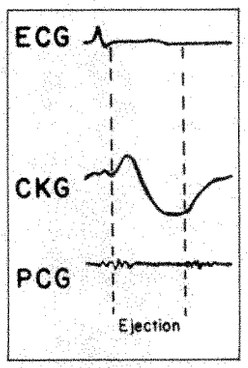

Fig. 4

I. Figure 1 is a pre-stress CKG™ (Cardiokymograph) tracing of the left ventricle (V3 position), it demonstrates:*

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

II. Figure 2 is a two minute post-stress CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

III. Figure 3 is a thirty minute post-stress resting CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

IV. Figures 1, 2 and 3, taken together, demonstrate:

- ☐ A. stress induced ventricular wall motion abnormalities consistent with ischemia
- ☐ B. normal ventricular wall motion

V. According to recently published[1] data, the CKG (Cardiokymograph) stress test is:

- ☐ A. 98% sensitive—98% specific
- ☐ B. 59% sensitive—69% specific
- ☐ C. 74% sensitive—95% specific
- ☐ D. 40% sensitive—60% specific

VI. Figure 4 is a photograph of:

- ☐ A. CKG/700 (Cardiokymograph)
- ☐ B. a noninvasive device that provides an analog representation of wall motion
- ☐ C. a low cost, simple device to be used in conjunction with stress testing to enhance diagnostic accuracy
- ☐ D. all of the above

For patients who need K^+Cl^- one sparkles bright:

KLORVESS® EFFERVESCENT GRANULES offer SPARKLING FAST DISSOLUTION

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

- **ready in *seconds* instead of minutes —fast dissolution so unique it's patented***
- **pleasant citrus flavor**
- **each packet delivers 20 mEq of potassium and chloride**
- **easily carried in patient's pocket or purse**
- **can be mixed with water or other liquid for pleasant daily dosage**
- **sugar, sodium, carbohydrate and dye free**

Give your patients the KLORVESS sparkle

Please see brief summary of prescribing information on adjoining page.

Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

☆ABP ABC

To prevent predictable angina*

CHEWABLE SORBITRATE®

(ISOSORBIDE DINITRATE) 5 mg. or 10 mg.

dependable, prolonged protection during periods of emotional or physical exertion.

Summary Of Prescribing Information

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: The chewable dosage form of SORBITRATE is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.
Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.
Precautions: Tolerance and cross tolerance to other nitrates may occur.
Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.
Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE* (isosorbide dinitrate) may be taken for prompt relief of angina pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.
Onset of Effect: Two to five minutes.
Duration of Effect: One to two hours.

CLINICAL STUDIES

721 Calcific Deposits in Porcine Bioprostheses: Structure and Pathogenesis

VICTOR J. FERRANS, STEVEN W. BOYCE, MARGARET E. BILLINGHAM, MICHAEL JONES, TOKUHIRO ISHIHARA and WILLIAM C. ROBERTS

Gross, histologic and ultrastructural analysis of 14 calcified porcine valve prostheses suggest that calcific deposits occur at all ages, but are usually more severe and clinically significant in children and young adults than in older patients. The calcific deposits limit the mobility of the cusps and may lead to prosthetic valve stenosis or regurgitation. The connective tissue in the cusps, particularly in the spongiosa, and small thrombi on the surfaces are the two main sites of such deposition of calcium phosphate. Calcification of connective tissue first involves the collagen fibrils; calcification of thrombi involves the mitochondria in platelets and leukocytes trapped in the mesh of fibrin. These deposits represent the results of different mechanisms that are discussed in depth.

735 Chronic Intravascular Hemolysis After Aortic Valve Replacement With Ionescu-Shiley Xenograft: Comparative Study With Bjork-Shiley Prosthesis

PEDRO R. FEBRES-ROMAN, WILSON C. BOURG, RICHARD A. CRONE, RICHARD C. DAVIS, Jr. and TROY H. WILLIAMS

This study of 20 patients with a prosthetic valve (Ionescu-Shiley or Bjork-Shiley) in the aortic position at a mean interval of 10.6 months after aortic valve replacement demonstrates a significantly greater incidence and degree of mild chronic intravascular hemolysis in the patients with the Ionescu-Shiley prosthesis than in those with the Bjork-Shiley prosthesis. The hemolysis appears to be related to the mechanical design of the prosthesis. No direct relation was found between serum lactic dehydrogenase or haptoglobin and valve size. It is also unlikely that an immune mechanism played a role. With time, endothelialization of the valve structures may lead to a lesser degree of erythrocyte destruction and hemolysis with the Ionescu–Shiley prosthesis.

739 Two Dimensional Echocardiographic Recognition of the Descending Thoracic Aorta: Value in Differentiating Pericardial From Pleural Effusions

WILLIAM S. HAAZ, GARY S. MINTZ, MORRIS N. KOTLER, WAYNE PARRY and BERNARD L. SEGAL

Using the location of the descending thoracic aorta on two dimensional echocardiography to differentiate pericardial from pleural effusions in 40 patients, these investigators found it constituted a valuable diagnostic aid. In this study 83 percent of the M mode studies were diagnostic in patients with a pericardial effusion. In 17 percent there was some difficulty in differentiating between a pericardial and pleural effusion. In these patients the location of the descending thoracic aorta on the two dimensional echocardiogram proved helpful. Combined pericardial and pleural effusions were visualized as echo-free spaces both anterior to and posterior and lateral to the descending thoracic aorta. The determination of the exact sensitivity and specificity of these findings awaits additional prospective study.

MULTI-PROGRAMMABLE
PULSE GENERATOR
DG2000177H
MEDTRONIC INC
MINNEAPOLIS, MN
USA

Medtronic leads the way to man's heart with Spectrax™-SX.

One of life's little miracles.

There is some tiny mystery inside a caterpillar that programs it to begin the new life of a butterfly. And for many adults and children, the Spectrax-SX pacemaker is their own little miracle. It's the smallest, most versatile programmable pacemaker yet, for atrial or ventricular demand pacing. It weighs a mere 45 grams. And many of your patients may never need a replacement.

With the Spectrax-SX pacemaker you can easily and noninvasively program a combination of eight parameters to precisely meet your patient's needs at any time during the pacemaker's potentially long service life.

The Spectrax-SX allows you to program and fine-tune pulse rate, pulse width, sensitivity, refractory period, hysteresis rate, amplitude and pacing mode (synchronous, asynchronous or demand.) It also has an automatic threshold safety margin check.

Medtronic's technological leadership in pacing, leads and support means you can offer many patients a more comfortable, normally active life with Spectrax-SX. And that's a little miracle.

Spectrax. Broadening the spectrum of precise patient management.

Medtronic

Leading the way to man's heart.

MEDTRONIC PRODUCT INFORMATION SUMMARY

Medtronic® Implantable Pulse Generators

Intended Uses—Ventricular pacing using an implantable ventricular pulse generator and lead system are for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems.

Contraindications—There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings—Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. (See product labeling for a complete list of warnings and precautions.)

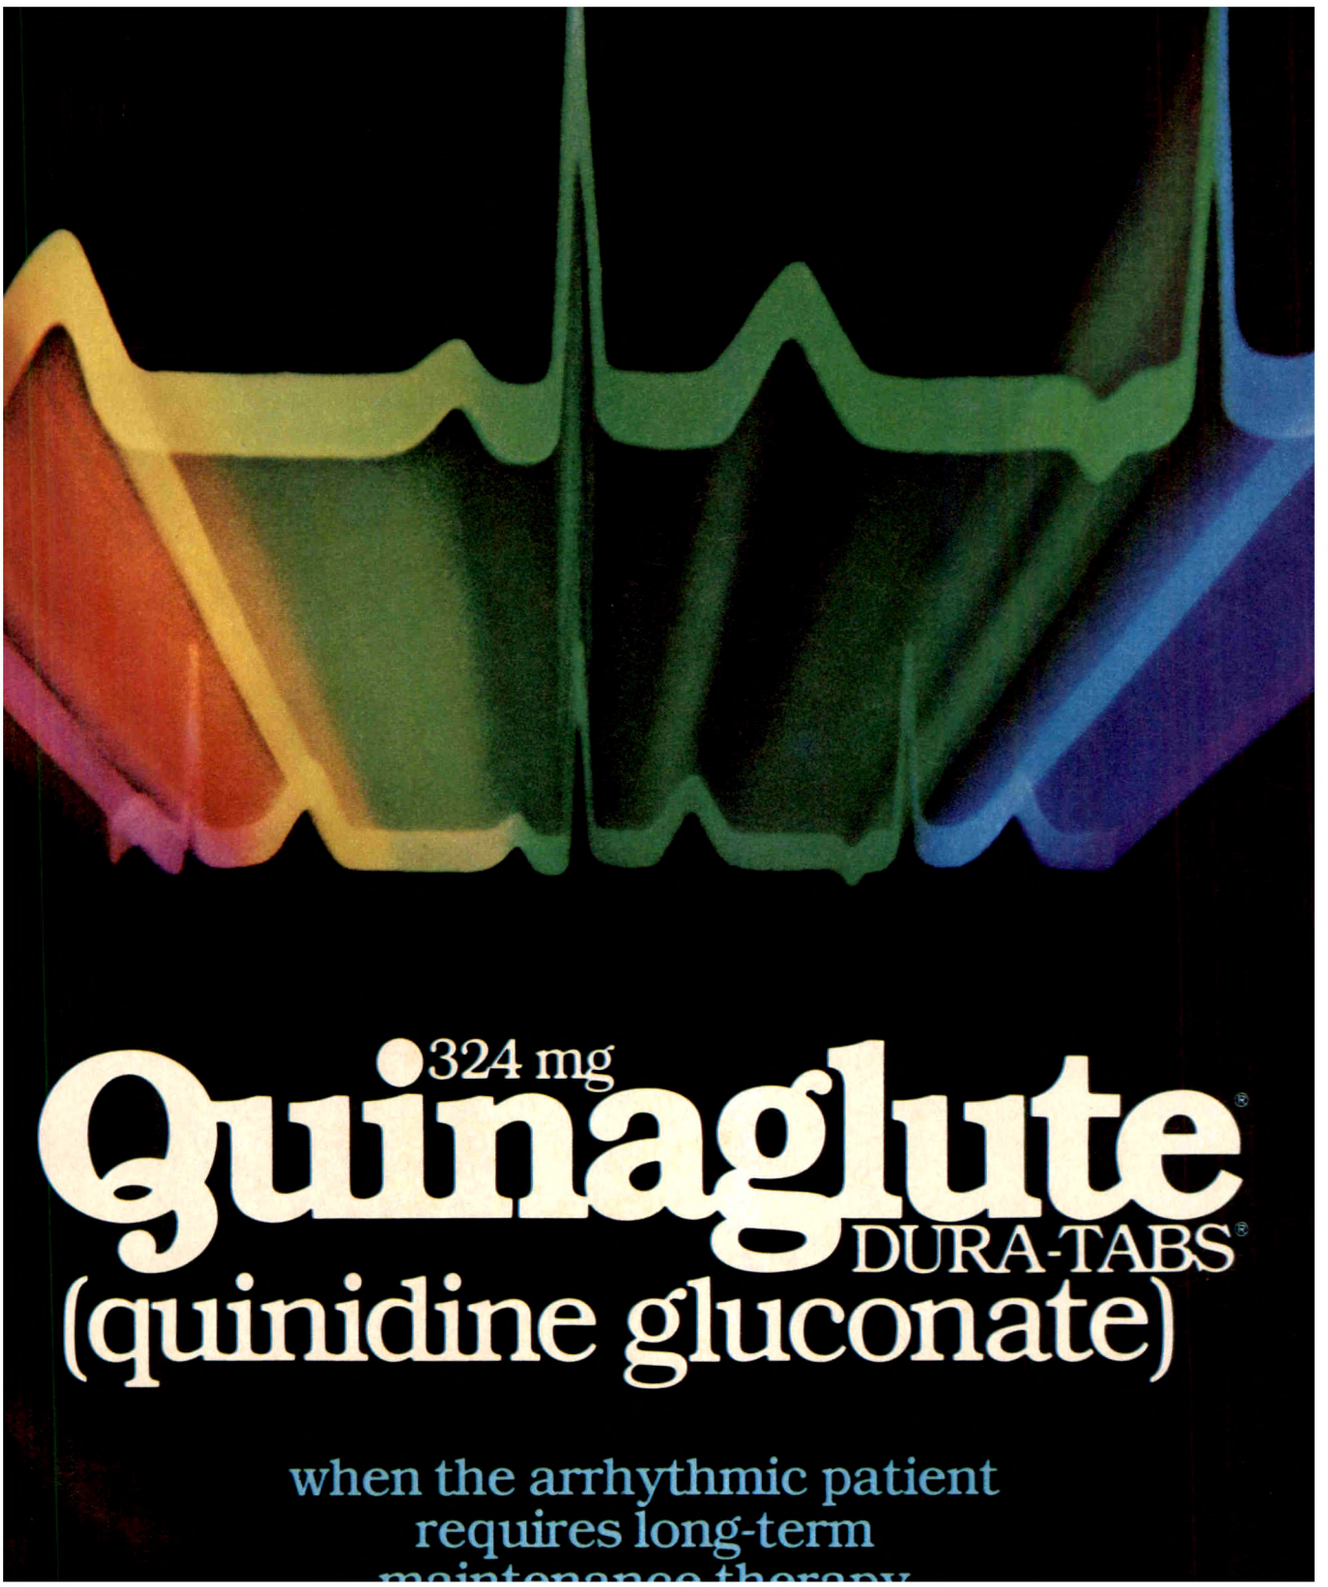
Precautions—The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects—Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

Model 9700/9701 Programmers

Intended Use—The Medtronic® Model 9700 and 9701 Programmers are designed to be used by a physician for noninvasively programming the Medtronic® pulse generators listed in their respective technical manuals. The programmers may also be used to measure the rate and pulse width of implanted pacemakers.

There are no known contraindications or major potential complications associated with use of the programmer. However, these devices should not be used without prior study of the technical manual supplied with each programmer.



Warnings—The programmers should only be used for programming the Medtronic® pulse generators designated in the respective technical manuals. Direct stimulation by energy coupling may occur if the programmers are used on other implanted devices. The programmers are not compatible with pulse generators of other manufacturers. See product labeling for a complete list of warnings and precautions.

When the compromised arrhythmic patient needs round-the-clock, year-after-year protection

324 mg Quinaglute® DURA-TABS® (quinidine gluconate)

CONTRAINDICATIONS:
Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.
Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening.
Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects, ventricular premature beats, ventricular tachycardia or flutter while on the drug.
Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.
Idiosyncrasy or hypersensitivity to quinidine.
WARNINGS:
In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.
PRECAUTIONS:
The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.
Quinidine in large doses may reduce the contractile force of the heart, therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication. The potential disadvantages and benefits must be weighed.
It should be administered cautiously, if at all, to senile patients.
Hospitalization for close clinical observation, electrocardiographic monitoring, and possibly plasma quinidine levels is indicated when large doses are used or with patients who present an increased risk.
ADVERSE REACTIONS:
Symptoms of cinchonism, ringing in ears, headache, nausea, disturbed vision may appear in sensitive patients after a single dose of the drug.
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism, hypotension.
Gastrointestinal: Nausea, vomiting, abdominal pain, diarrhea.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision fields, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Cutaneous flushing with intense pruritus.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.
See package insert for full information.

744 Histologic and Ultrastructural Features of Normal Human Parietal Pericardium

TOKUHIRO ISHIHARA, VICTOR J. FERRANS, MICHAEL JONES, STEVEN W. BOYCE, OICHI KANANAMI and WILLIAM C. ROBERTS

Histologic and transmission and scanning electron microscopic observations on normal human parietal pericardium indicate that the pericardial mesothelial cells of the serosa have single cilia and are covered with microvilli that bear friction and increase the surface area for fluid transport. Actin-like filaments (50 Å in diameter) in the microvilli and in immediately subjacent regions mediate change in cell shape. Intermediate filaments (100 Å in diameter) are associated with desmosomes, form bundles in the perinuclear regions, and provide structural support to the cytoplasm. The observations demonstrate the complexity of the organization of the various structural components of human parietal pericardium and illustrate the range of adaptations this tissue has developed to perform its functions. The connective tissue permits only a limited amount of stretch, which is mediated by straightening of the wavy arrangement of bundles of collagen fibrils.

754 True Left Ventricular Aneurysm and Healed Myocardial Infarction. Clinical and Necropsy Observations Including Quantification of Degrees of Coronary Arterial Narrowing

HENRY S. CABIN and WILLIAM C. ROBERTS

In this clinicopathologic study of 28 necropsy patients with left ventricular aneurysm it was found that the myocardial infarction is large, the nonscarred left ventricular wall is hypertrophied, the left ventricular cavity is dilated, and the major epicardial arteries are severely narrowed. Chronic congestive heart failure is frequent and the major cause of death, but chest pain, arrhythmia, recurrent myocardial infarction and systemic embolism are infrequent. The clinical diagnosis by means other than left ventricular angiography is infrequently made.

764 Response to Exercise Early After Uncomplicated Acute Myocardial Infarction in Patients Receiving No Medication: Long-Term Follow-Up

GERALD M. KOPPES, WILLIAM KRUYER, CHARLES H. BECKMANN and FREDERIC G. JONES

Submaximal treadmill exercise testing 3 weeks after an uncomplicated acute myocardial infarction in 90 patients on no medication proved safe and provided reference values for safe limits in performing maximal treadmill testing at 8 weeks after infarction. S-T segment changes or angina, or both, the inability to complete a maximal 8 week treadmill test identified patients at risk for later complications. Exercise variables at submaximal equivalent exercise work did not change from 3 to 8 weeks. At maximal exercise 15.6 percent of the patients had S-T changes alone, 8.9 percent had angina pectoris alone and 12.2 percent had both. In all, fatigue, progressive shortness of breath or leg discomfort rather than angina was the exercise end point. Modified treadmill testing at 3 weeks and maximal testing at 8 weeks after acute myocardial infarction under controlled circumstances are more safely performed than unmonitored home management and follow-up of such patients.

770 Improvement in Ventricular Function During Exercise Studied With Radionuclide Ventriculography After Cardiac Rehabilitation

DAVID JENSEN, J. EDWIN ATWOOD, VICTOR FROELICHER, M. DAN McKIRNAN, WILLIAM ASHBURN and JOHN ROSS, Jr. with the technical assistance of JUDY SASSONE, MARY LOU STRONG and JULIE FROELICHER

This study using radionuclide ventriculography to assess left ventricular function at rest and during exercise before and after a training program in 19 patients with coronary artery disease showed that after training the subjects achieved a higher maximal mean systolic blood pressure, heart rate and work load, but no change in mean ejection fraction at rest or during maximal exercise. At equivalent submaximal work loads after training, similar levels of mean heart rate and systolic blood pressure were reached and a statistically greater mean ejection fraction was obtained. Data in four patients with coronary bypass grafting also indicate exercise training benefited them. Since spontaneous improvement in function may follow a myocardial infarction, controlled larger studies are needed to document further these preliminary findings and to assess which patients respond most favorably to exercise training as a mode of therapy.

continued on page A22

You May Be Mis-Diagnosing Your Holter Patients.

The incompleteness of Holter scan reports with unverifiable numbers and trends are the reasons. Less than 1% of the Holter ECG data is normally presented for your diagnosis. What happened the other 99% of the time?

1979 brought a breakthrough in Holter monitoring. The development of micro-computer controlled fiberoptics made it possible to print every ECG complex into a textbook format, providing twenty-four, hourly pages of ECG data.

No matter who the operator, the report is identical every time, and only takes three minutes to generate. Plus, this report is faster and easier to read than that of conventional Holter equipment.
The major difference is "Assurance".

The product is The Eliminator™ by AdvanceMed, now a part of American Hospital Supply Corporation. The Eliminator is the first to offer 100% accurate ECG data and is available at half the price of average Holter equipment.

You owe it to yourself and to your patients to see The Eliminator. Since it is compatible with most Holter recording systems, call or write and we'll run one of your tapes.
You May Be Surprised To See What You Are Missing!

Because of the way Inderal® (propranolol HCl) works, the anginal heart doesn't have to work so hard

Consider the anginal heart at stress: It works harder, faster. Needs more oxygen. Pumps harder, faster still. Strives for more oxygen—with pain. Anginal attack means more nitroglycerin. And that means faster heart rate. The cycle repeats.

Consider Inderal: It reduces heart rate—therapeutically—by some 12 beats a minute.[1-6] 720 fewer beats per hour. Some 6 million fewer beats per year. That means less work for the anginal heart. Less oxygen demand by the myocardium. Fewer anginal attacks. Less need for sublingual nitroglycerin. More tolerance for exercise—and more freedom of action.

Reduction in heart rate is modest: should not be cause for concern.[7] The relatively low dosages required for angina prophylaxis (an average of 160 mg/day) produce few, if any, serious adverse reactions, which in any case are readily recognized and controlled.

With proper patient selection—in the absence of bronchial asthma, sinus bradycardia, or heart block greater than first degree—risk of precipitating cardiac failure is extremely rare. And withdrawal problems may be avoided by reducing dosage gradually—rather than abruptly.*

Consider too: There is also a favorable redistribution of perfusion to the vulnerable subendocardium.[8] And, in patients who may still need nitroglycerin p.r.n., INDERAL will cancel the undesirable increase in heart rate and contractility.

Prescribe INDERAL with confidence. Effective. Reliable. For patients with moderate to severe angina in whom conventional measures have failed.

*For full information on Contraindications, Precautions, Adverse Reactions, and Warnings, including avoidance of abrupt withdrawal, please consult the prescribing information on the following page.

INDERAL®
(PROPRANOLOL HCl)
TODAY'S 40mg 80mg tabs.
BENCHMARK
FOR **ANGINA PROPHYLAXIS**

Ayerst®

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® BRAND OF
PROPRANOLOL HYDROCHLORIDE
A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support.

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATION

Angina Pectoris Due to Coronary Atherosclerosis: The initial treatment of angina pectoris involves weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances. INDERAL is indicated in selected patients with moderate to severe angina pectoris who have not responded to these conventional measures. Propranolol should not be used in patients with angina which occurs only with considerable effort or with infrequent precipitating factors.

INDERAL exerts both favorable and unfavorable effects, the preponderance of which may be beneficial. (See ACTIONS Section.) INDERAL should not be continued unless there is reduced pain or increased work capacity.

Because of the potential for adverse results, treatment should be carefully monitored. The patient should also be reevaluated periodically since the dosage requirement and the need to continue INDERAL may be altered by clinical exacerbations or remissions. (See DOSAGE AND ADMINISTRATION.)

Additional studies of the effects of INDERAL in angina pectoris patients are in progress to better evaluate and define the proper role of INDERAL in this condition.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.*, that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCH EMPHYSEMA), INDERAL should be administered with caution since it may block broncho tion produced by endogenous and exogenous catecholamine stimulation of beta receptor

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrene blocking activity, INDERAL may prevent the appearance of premonitory signs and sympto (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to k in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a p cipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been es- tablished. Use of any drug in pregnancy or women of childbearing potential requires that t possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. bryotoxic effects have been seen in animal studies at doses about 10 times the maximum r ommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug then produce an excessive reduction of the resting sympathetic nervous activity. Occasion the pharmacologic activity of INDERAL may produce hypotension and/or marked bradyca resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be ob served at regular intervals. The drug should be used with caution in patients with impaired or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypoten paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, l tude, weakness, fatigue; reversible mental depression progressing to catatonia; visual dist bances; hallucinations; an acute reversible syndrome characterized by disorientation for ti and place, short term memory loss, emotional lability, slightly clouded sensorium, and de- creased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, c stipation, mesenteric arterial thrombosis, ischemic colitis

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with achir and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpu

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, s ous membranes and conjunctivae reported for a beta blocker (practolol) have not been co sively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe hear ease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION

The dosage range for INDERAL is different for each indication.

ORAL

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 10-20 mg three or fo times daily, before meals and at bedtime, dosage should be gradually increased at three t seven day intervals until optimum response is obtained. Although individual patients may r spond at any dosage level, the average optimum dosage appears to be 160 mg per day. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several wee (See WARNINGS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit ade- quate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING M SURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg): IF THERE IS NO RESPON TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.*, LEVARTERENOL OR EPINEPHRINE (THERE EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL
(propranolol hydrochloride)

TABLETS

No. 461—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 10 1,000. Also in unit dose package of 100.

No. 462—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 10 1,000. Also in unit dose package of 100.

No. 464—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 10 1,000. Also in unit dose package of 100.

No. 468—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 10 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The p adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

"Hello, Clinical Data!?...when we cancelled your Holter service last year to go to a cheaper service?... well...we...I was wondering if..."

We call it the "lowest bidder syndrome."

The Problem.
Subscribing to a Holter service by calculator rather than quality.

The Symptoms.
Paying less... and getting less.

Less recording capability. Due to artifact prone recorders. Recharged batteries that really ought to come with jumper cables. And patient cables you wouldn't use to string twinkle lights on your Christmas tree.

Less reviewing capability. Due to skeleton crews, fewer shifts, and the use of flickering superimposition techniques that could make any technician run to a disco just to rest her eyes.

Less reporting quality. Due to unsubstantiated ectopic summaries (which may be automatically generated).

Because of fewer tracings in support of reported abnormalities. And because of presentation formats that can be harder to read (and pronounce) than Dostoyevski in Hindustani.

The Cure.
Choose Clinical Data, and stay with Clinical Data. Get more, and more, and more... of More.

More recording capability. Because of an FM recorder that is less prone to artifact. And that uses one-time-only disposable batteries.

More reviewing capability. Because of our many reviewing systems that operate 24-hours a day, seven days a week. Because of our own Stein/Peterson™ Technique in which the *entire recording* is presented in consecutive two-minute segments on a 19-inch screen at a rate controlled by the examiner.

More reporting capability. Because of a report that includes standard ECG strips, hourly hear rate, and graphic and numerical quantitation of up to eight different ectopic foci validated by the examiner.

More quality control. Because each report is reviewed before it is delivered, and because our separate Q.C. department routinely checks each examiner.

Even if you've seen one of Clinical Data's LCG Reports, you haven't really seen one of Clinical Data's *new* LCG Reports. We've made the best even better. Call or write. We'll send you one.

778 Relation of Exercise-Induced Physiologic S-T Segment Depression to R Wave Amplitude in Normal Subjects

MYRON C. GERSON, STEPHEN N. MORRIS and PAUL L. McHENRY

Exercise electrocardiographic data obtained in 100 asymptomatic male volunteers with a mean age of 42.6 years demonstrated a significant relation between the magnitude of R wave and total RS amplitudes and the magnitude of physiologic S-T segment depression. These findings suggest a need to evaluate S-T depression corrected for R wave amplitude because the sensitivity and specificity of the exercise electrocardiogram may be improved by correcting the amount of S-T depression for the magnitude of R wave amplitude. Criteria for abnormal S-T depression should include consideration of the different R wave voltages in the different types of recording leads.

EXPERIMENTAL STUDIES

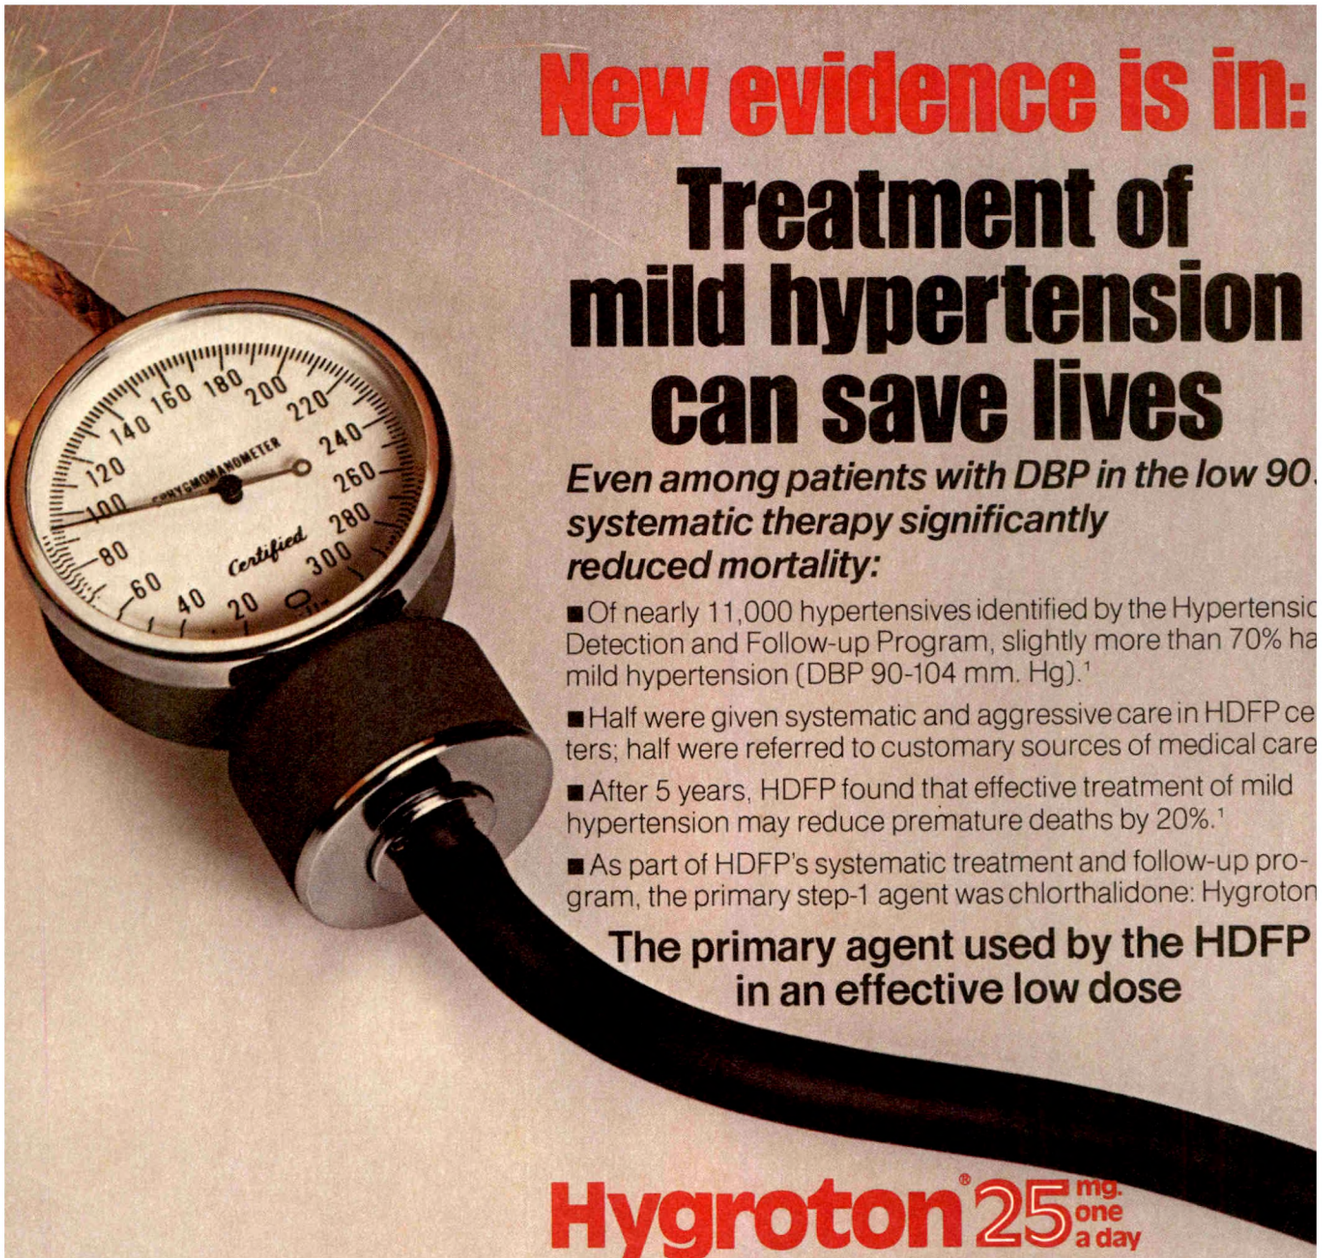
783 Continuous Fractionated Electrical Activity After Stimulation of the Ventricles During the Vulnerable Period: Evidence for Local Reentry

DAVID E. EULER and E. NEIL MOORE

Ventricular multiple extrasystoles and fibrillation were induced in open chest dogs by the delivery of a single electrical pulse or a train of pulses to the right ventricle during the vulnerable period of the cardiac cycle. The presence of continous local electrical activity before the development of multiple extrasystoles and fibrillation supports the thesis that the ventricular fibrillation threshold technique operates by producing local reentrant activity. The current required to produce continuous electrical activity and fibrillation with a train of pulses in this study was consistently less than that required for a single pulse. When continuous electrical activity disappeared during a run of extrasystoles, there was prompt resumption of normal sinus rhythm. Also, when such continuous electrical activity was produced by a single stimulus during the vulnerable period, it could be abolished by a second stimulus delivered during the protective zone.

792 Electrophysiologic Effects of Disopyramide Phosphate on Reentrant Ventricular Arrhythmia in Conscious Dogs After Myocardial Infarction

EUGENE PATTERSON, JOHN K. GIBSON and BENEDICT R. LUCCHESI



Evaluation of the electrophysiologic actions of disopyramide phosphate on reentrant ventricular tachycardia in conscious dogs 2 to 4 days after myocardial infarction demonstrates plasma therapeutic concentration in excess of the normal therapeutic range of 2 to 4 μg/ml are necessary to prevent ventricular tachycardia or fibrillation, or both. Lesser concentrations of 1.02 $\pm$ 0.02 μg/ml increased the rate and duration of ventricular tachycardia as well as the duration of the interval during which premature ventricular stimuli produced ventricular tachycardia. Subtherapeutic concentrations may facilitate the development of reentrant ventricular arrhythmia in the electrically unstable heart. There is evidence that plasma concentrations of antiarrhythmic agents necessary to prevent sudden coronary death may be higher than currently accepted "therapeutic" concentrations. However, the negative inotropic effect of disopyramide may preclude the use of higher dosage regimens in patients with compromised left ventricular function.

800 The No Reflow Phenomenon: A Time-Limiting Factor for Reperfusion After Coronary Occlusion?

JOHN R. DARSEE and ROBERT A. KLONER

The "no reflow" phenomenon, as analyzed in 33 dogs, does not determine the critical time for salvageability of infarcted myocardium by revascularization because the area of no reflow is surrounded by necrotic but reperfusable tissue. Reperfusion does not increase the quantity of ischemic tissue that becomes necrotic. The area of necrosis expressed as a percent of the area at risk was significantly smaller for dogs with 2 or 4 hours of occlusion and reperfusion than for dogs with longer periods of occlusion and briefer periods of reperfusion. The quantity of ischemic but still viable tissue is influenced primarily by the duration of the period between the onset of ischemia and the time of the intervention, and not by the existence, distribution or spatial geometry of the no flow phenomenon. Although the occurrence of the no reflow phenomenon in human subjects has not yet been determined, its presence could have important clinical implications for drug therapy and coronary bypass grafting.

New evidence is in:

Treatment of mild hypertension can save lives

Even among patients with DBP in the low 90s, systematic therapy significantly reduced mortality:

- Of nearly 11,000 hypertensives identified by the Hypertension Detection and Follow-up Program, slightly more than 70% had mild hypertension (DBP 90-104 mm. Hg).[1]
- Half were given systematic and aggressive care in HDFP centers; half were referred to customary sources of medical care.
- After 5 years, HDFP found that effective treatment of mild hypertension may reduce premature deaths by 20%.[1]
- As part of HDFP's systematic treatment and follow-up program, the primary step-1 agent was chlorthalidone: Hygroton.

The primary agent used by the HDFP in an effective low dose

Hygroton® 25 mg. one a day
(chlorthalidone USP)

Because there's nothing mild about mild hypertension

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs. **Warnings:** Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn. **Usual Dose:** One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored), 50 mg. (aqua) in bottles of 100, 1000 and 5000; 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips).

Your diagnosis depends

In noninvasive diagnosis, superior image quality provides the greatest assurance of rapid and reliable diagnosis, and maximum patient throughput. The ATL Mark III Cardiology System is designed to routinely provide ultrasound images of this outstanding quality.

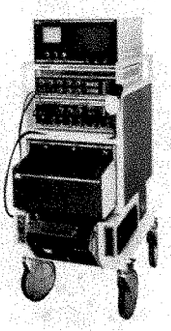
Why are ATL images outstanding?

The images produced by th Mark III Cardiology System clearly demonstrate its abili produce quality. We invite y to examine the left ventricu posterior wall. Notice the sh resolution of the endocardia surface enabling analysis of motion, wall thickness and l ventricular chamber size. B optimizing the gray scale di bution curve, ATL images cl define the endocardium, epi cardium and pericardium fo your study. Further, the card valves are accurately define And the cavities are clean a clearly imaged.

up rior im: qu: lity. ATL-d liv rs.

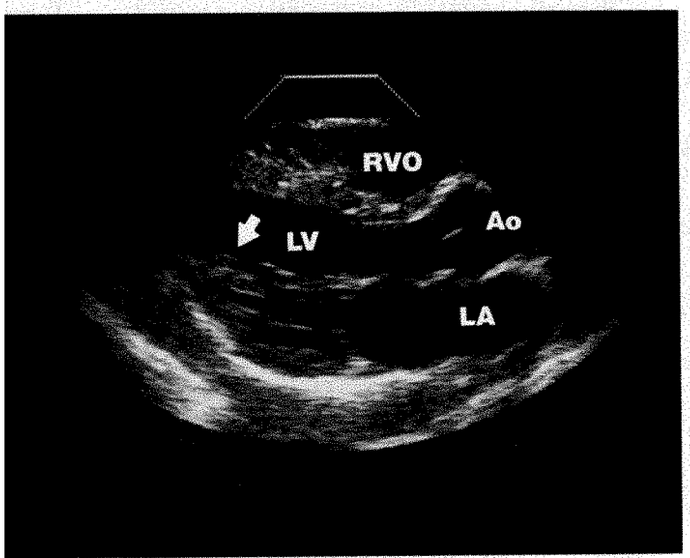
A systems approach to clinical capabilities.

Although the Mark III Cardiology System produces ultrasound images of outstanding quality, its clinical capabilities don't stop there. The system is also modular with the capability of being upgraded by addition of pulsed Doppler flow detection. It is fully mobile for critical care examinations, and provides a choice of 3 MHz high resolution scan head for adult examinations or an optional 5 MHz scan head for neonatal use.



Because of its superb digital scan conversion, the Mark III Cardiology System offers both 2-D video format with an excellent freeze frame which is ECG-triggered and digital M-Mode. Also available is a new line scan recorder that makes excellent hard copy available for your records.

Consider the value/price/performance ratio.



When you compare image quality and other key benefits, you will find that the Mark III Cardiology System provides the most favorable value/price/performance ratio in the field. For complete technical details, please contact your local ATL representative or call or write Advanced Technology Laboratories, Inc.

METHODS

807 Methodologic Problems of Exercise Testing for Coronary Artery Disease: Groups, Analysis and Bias

JOHN T. PHILBRICK, RALPH I. HORWITZ and ALVAN R. FEINSTEIN

Exercise testing remains controversial as a diagnostic test for coronary artery disease because of methodologic problems that produce a wide range of sensitivity (35 to 88 percent) and specificity (41 to 100 percent). In this review of 33 studies of 7,501 patients subjected to stress testing and coronary angiography, there was general compliance with only one of the seven standards used in this evaluation—adequate analysis of anatomic lesions. Less than half of the studies complied with any of the remaining six standards. The main conclusion is that exercise testing research should be made more clinically relevant. For this, investigators must pay greater attention to the basic methodologic design of patient selection, data collection and data analysis. But even with an improved basic design, the sensitivity and specificity of an exercise test may remain highly variable because the coronary arteriogram measures anatomic abnormalities whereas the exercise test measures the heart's physiologic response to increased work.

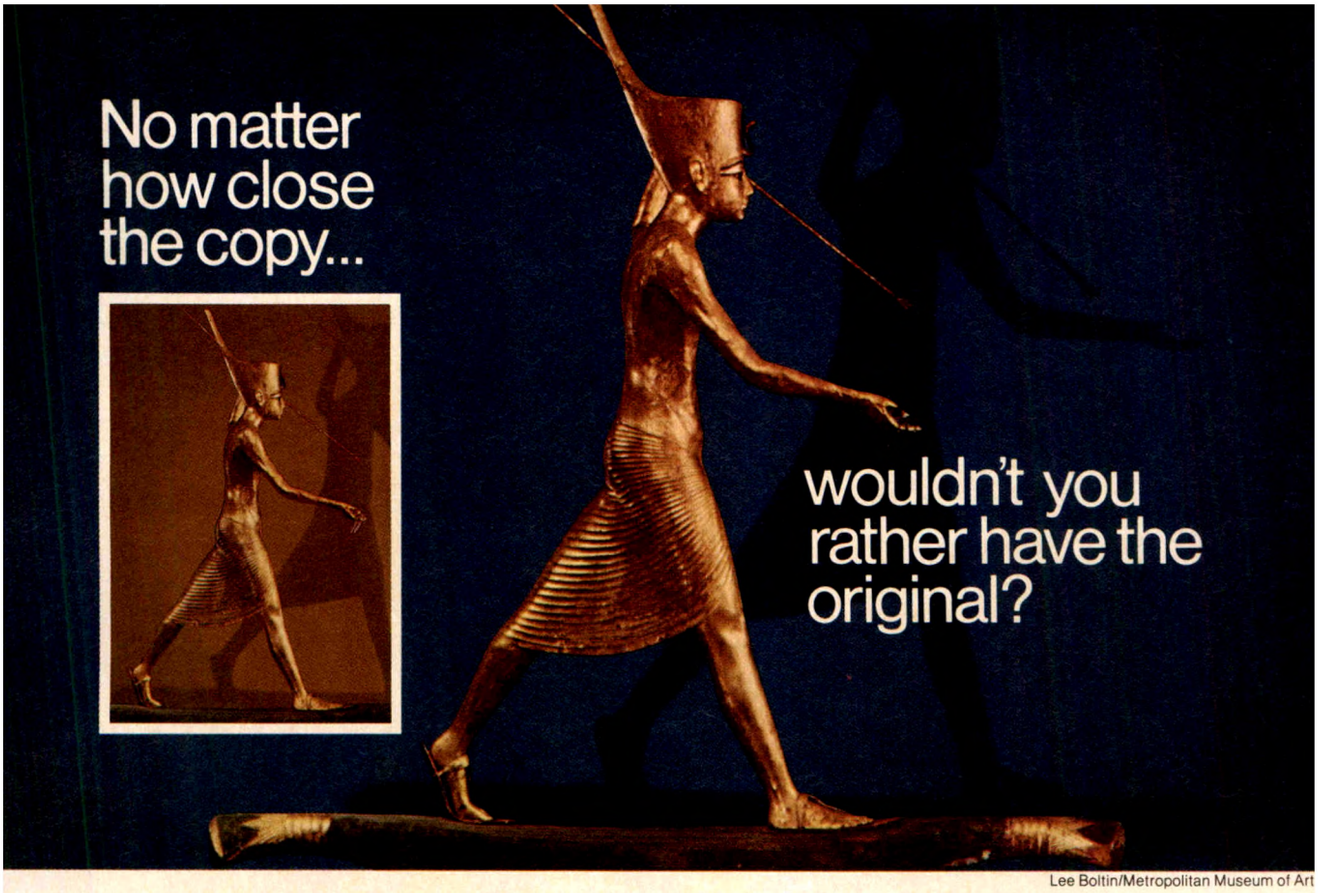
813 Peak Systolic Blood Pressure/End-Systolic Volume Ratio: Assessment at Rest and During Exercise in Normal Subjects and Patients With Coronary Heart Disease

ROBERT SLUTSKY, JOEL KARLINER, KENNETH GERBER, ALEXANDER BATTLER, VICTOR FROELICHER, GABRIEL GREGORATOS, KIRK PETERSON and WILLIAM ASHBURN

Using equilibrium radionuclide angiography to determine end-systolic volume and the systolic blood pressure obtained by cuff sphygmomanometer to determine peak systolic pressure these investigators found that the end-systolic pressure/volume ratio is a useful index of left ventricular performance. In some patients this ratio during supine exercise stress is more sensitive than the ejection fraction in identifying the presence of left ventricular dysfunction. The limitations of the method depend on the variability of the radionuclide technique and the accuracy with which the peak systolic blood pressure can represent the peak left ventricular systolic pressure. The noninvasive result tends to overestimate the actual ratio mainly because the brachial arterial pressure reflects an amplified left ventricular pressure wave secondary to the arterial compliance and pressure waveform of reflectance.

821 Influence of Coronary Artery Disease on Pulmonary Uptake of Thallium-201

JOHN B. BINGHAM, KENNETH A. McKUSICK, H. WILLIAM STRAUSS, CHARLES A. BOUCHER and GERALD M. POHOST with the technical assistance of FREDERICK A. GODLEY



Animal and human studies on the pulmonary uptake of thallium-201 suggest that the increased pulmonary concentration of this isotope during exercise is a consequence of left ventricular failure. In dogs balloon obstruction of the left atrium (which increased mean left atrial pressure and pulmonary transit time) and the administration of acetylcholine (which prolonged pulmonary transit time only) increased the extraction fraction of thallium-201 by the lungs from the basal value of 0.09 ± 0.009 at rest to 0.19 ± 0.02. Quantitation of lung activity of 86 patients indicated that the increased ratio of initial/final pulmonary thallium-201 activity in 30 patients with multivessel coronary artery disease was due to a transient absolute increase in the thallium-201 concentration immediately after maximal exercise. Increased lung uptake in the initial images of a thallium stress study should alert the observer to an underlying impairment of left ventricular function.

827 Effect of Selective Coronary Arteriography on Left Ventricular Volumes and Ejection Fraction in Man

LAWRENCE STERN, BRIAN G. FIRTH, GREGORY J. DEHMER, STACEY M. JOHNSON, ROY V. MARKHAM, SAMUEL E. LEWIS and L. DAVID HILLIS

Contrast left ventriculography and selective coronary arteriography are associated with complex changes in ventricular function and circulatory hemodynamics. In this study of 30 patients with assorted cardiac diseases selective coronary arteriography consistently increased left ventricular end-diastolic pressure from 13.0 ± 6.5 mm Hg before coronary arteriography to 16.1 ± 7.0 mm Hg immediately after but did not affect left ventricular volumes or ejection fraction, even in those with severely compromised left ventricular function. Intracardiac pressures should therefore be measured before the injection of radiographic contrast material, but left ventricular volumes and ejection fraction can be quantitated at any time during catheterization. It may be preferable to assess coronary arterial anatomy first in patients in clinically unstable condition and then evaluate left ventricular volumes and ejection fraction.

Lee Boltin/Metropolitan Museum of Art

The original dipyridamole.

Persantine®
(dipyridamole)

INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and /or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine tablets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.

ADVERSE REACTIONS— Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25 mg and 75 mg

Bayer® Aspirin

For reducing the risk of transient ischemic attacks or stroke in men who have had transient ischemia c the brain due to fibrin platelet emboli

THE DAWN OF A NEW ERA IN PREVENTIVE MEDICINE

Recently, an official government bulletin indicated that the following professional guideline labeling will be published:

There is evidence that aspirin is safe and effective for reducing the risk of recurrent transient ischemic attacks or stroke in men who have had transient ischemia of the brain due to fibrin platelet emboli.

There is no evidence that aspirin is effective in reducing TIA's in women, or is of benefit in the treatment of completed strokes in men or women.

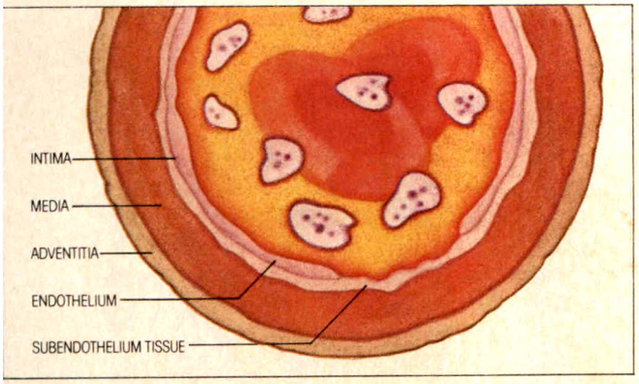
Patients presenting with signs and symptoms of TIA's should have a complete medical and neurologic evaluation.

Consideration should be given to other disorders which resemble TIA's.

It is important to evaluate and treat, if appropriate, other diseases associated with TIA's and stroke, such as hypertension and diabetes.

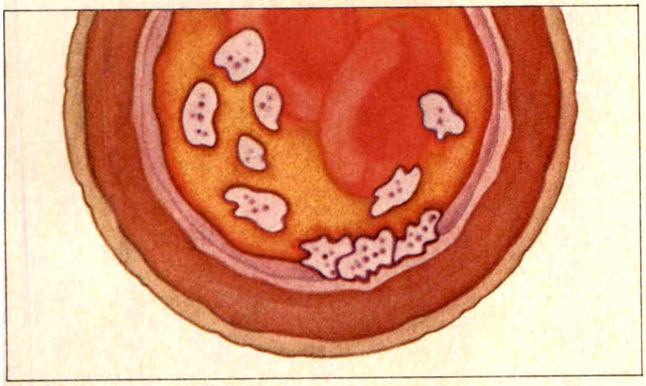
The recommended dosage for this new indication is 1,300 mg/day (650 mg twice/day or 325 mg four times a day).

Prostaglandin inhibition— the key to aspirin's succes



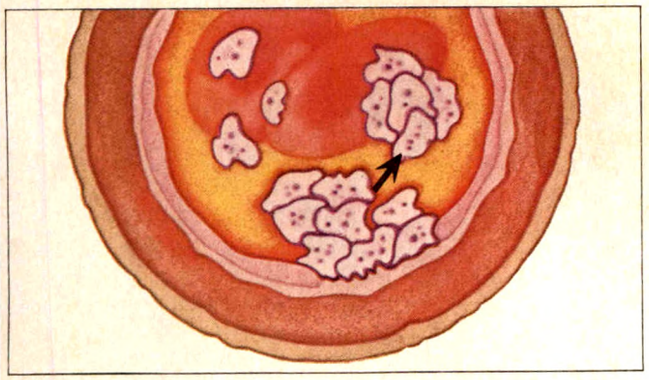
With the ability of aspirin to reduce the risk of recu rent TIA's and stroke clearly demonstrated in tw major multicenter studies,[1,2] physicians throughou the country can now provide their own TIA patien with the prophylactic benefits of Bayer Aspirin.

At the same time, important new research being conducted to determine the full scope aspirin benefits in vascular disease...and in mar other disorders involving prostaglandin synthesis



It has become apparent that many of aspirir therapeutic effects—including its analgesic, an pyretic, anti-inflammatory and antithrombot actions, can be traced entirely, or in part, to i ability to inhibit prostaglandin formation.

Prostaglandins are produced by every orga in the body with far reaching effects.[3] In vascula disease, for example, it is the excess productic of the prostaglandin derivative, thromboxane A that can ultimately lead to embolus formation.



Cross-section of artery—artist's interpretation of circulating platelets encountering area of erosion in arterial wall.

Cerebrovascular clot formation begins when platelets circulating in the blood encounter an area of vascular erosion (usually predisposed by atherosclerosis)...with its exposed subendothelial tissue and collagen.

Through a series of prostaglandin interactions, a platelet collagen reaction takes place—first provoking platelet adhesion, then stimulating a self-perpetuating process of secretion, and finally, aggregation. Once formed, thrombi may dislodge.

By inhibiting platelet cyclo-oxygenase, an enzyme that mediates prostaglandin formation, aspirin inhibits thromboxane synthesis, prevents adhesion and thrombus formation and precludes thrombus dislodgment and subsequent TIA or stroke.

Bayer Aspirin and continuing investigations

Of the large number of pharmaceutical agents capable of altering platelet function, only aspirin has been shown to produce effects that are irreversible for the life of the platelet.[4]

Thus, the use of aspirin is being intensively investigated in a number of possible new clinical areas in which its antiplatelet, prostaglandin-inhibiting effects may be beneficial.

Not surprisingly, Bayer Aspirin has been the aspirin chosen for a large number of past and present studies. Bayer Aspirin actually exceeds U.S.P. requirements in critical areas such as aspirin content per tablet, disintegration time and free salicylic acid content. Over 100 quality-control tests help assure that the therapeutic dose recommended is the dose patients receive.

The Bayer Company is pleased not only to lend its continuing support to wide-ranging investigational studies, but to provide the medical community with comprehensive services and materials concerning aspirin.

The ability to reduce the risk of TIA or stroke with a drug as widely accepted, well tolerated and inexpensive as Bayer Aspirin, certainly represents the dawn of a new era in preventive medicine.

832 Semiautomated Method for Evaluation of Left Ventricular Regional Wall Motion in Coronary Artery Disease

SANFORD E. WARREN, VALMIK BHARGAVA, WALTER V. R. VIEWEG, GEORGE W. DENNISH, JOSEPH S. ALPERT and ARTHUR D. HAGAN

This correlation of subjective visual inspection of regional left ventricular wall motion with objective computer-determined percent change in the square root of the area between systolic and diastolic outlines in 436 ventriculograms suggests that the latter technique is valuable as both a check on subjective ventriculographic readings and a permanent quantitative document. This study was not designed to and does not resolve whether the computer or the subjective technique is more correct, but it examines objective regional wall motion analysis in the light of current practice (subjective analysis).

837 High Speed Rotating Scanner for Transesophageal Cross-Sectional Echocardiography

KOHZOH HISANAGA, ASAKO HISANAGA, NORIO HIBI, KINYA NISHIMURA and TADASHI KAMBE

Use of a newly developed transesophageal ultrasonic rotating scanner that rotates a single transducer through a full 360° in the esophagus at a rate of 15 to 50 cycles produced high quality images of most portions of the heart with no serious complications and only slight gagging. This system provides a wider area for study of the heart than is available with a conventional external system. Future applications include the detection of left atrial thrombus, demonstration of a much larger area of both ventricles than is obtained with external views, and easier analysis of right and left ventricular anterior wall motion and of valve diseases and disorders. As yet, this method is difficult to perform in infants or children without sedation.

PEDIATRIC CARDIOLOGY

843 Prognostic Significance of Arrhythmia in Tetralogy of Fallot After Intracardiac Repair

HANS U. WESSEL, CHRISTIAN K. BASTANIER, MILTON H. PAUL, TERESA E. BERRY, ROGER B. COLE and ALEXANDER J. MUSTER

This study of the significance of arrhythmia and conduction defects in 395 patients subjected to intracardiac repair of tetralogy of Fallot between 1958 and 1976 shows no tachyarrhythmias, less first degree atrioventricular block and more complete right bundle branch block in patients more recently operated on. The overall incidence of arrhythmia events on routine electrocardiography was 19 percent. There was not a large incidence of severe ventricular arrhythmia when ventricular ectopic rhythm was present at rest. In the majority of these patients ventricular arrhythmia was suppressed when the sinus rate approached or exceeded the rate of the ectopic pacemaker during exercise. Exercise induced no tachyarrhythmia. Arrhythmias were least common in patients with primary intracardiac repair and more common in those with palliation before intracardiac repair or with multiple intracardiac repairs. Patients with arrhythmia or bifascicular block usually had a benign course without strong evidence of arrhythmia progression.

849 Pulsed Doppler Echocardiographic Evaluation of the Cyanotic Newborn: Identification of the Pulmonary Artery in Transposition of the Great Arteries

JAMES GEOFFREY STEVENSON, ISAMU KAWABORI and WARREN G. GUNTHEROTH

In a series of 68 cyanotic neonates with two ventricles and two great vessels, pulsed Doppler echocardiography established that ductal patency is prevalent in the cyanotic neonates, that detection of ductal flow can define the pulmonary artery and that such definition helps resolve the question of transposition of the great arteries in infants with a relation of the great vessels that is neither normal nor suggestive of transposition. On M mode examination the relations of the great vessels were normal in 43 infants; pulsed Doppler echocardiography detected a patent ductus arteriosus flowing into a normally positioned pulmonary artery in all. The cyanosis in all 43 was later proved to be of pulmonary origin. Pulsed Doppler echocardiography equipment is less expensive. The method provides physiologic input into the great vessel diagnosis by identifying the pulmonary artery and screening for severe pulmonary hypertension and intracardiac defects that may not be detectable by other noninvasive means. It reduces the need for cyanotic neonates to undergo cardiac catheterization.

If you think the EK-8 is a fast recorder, see how it saves mounting time!

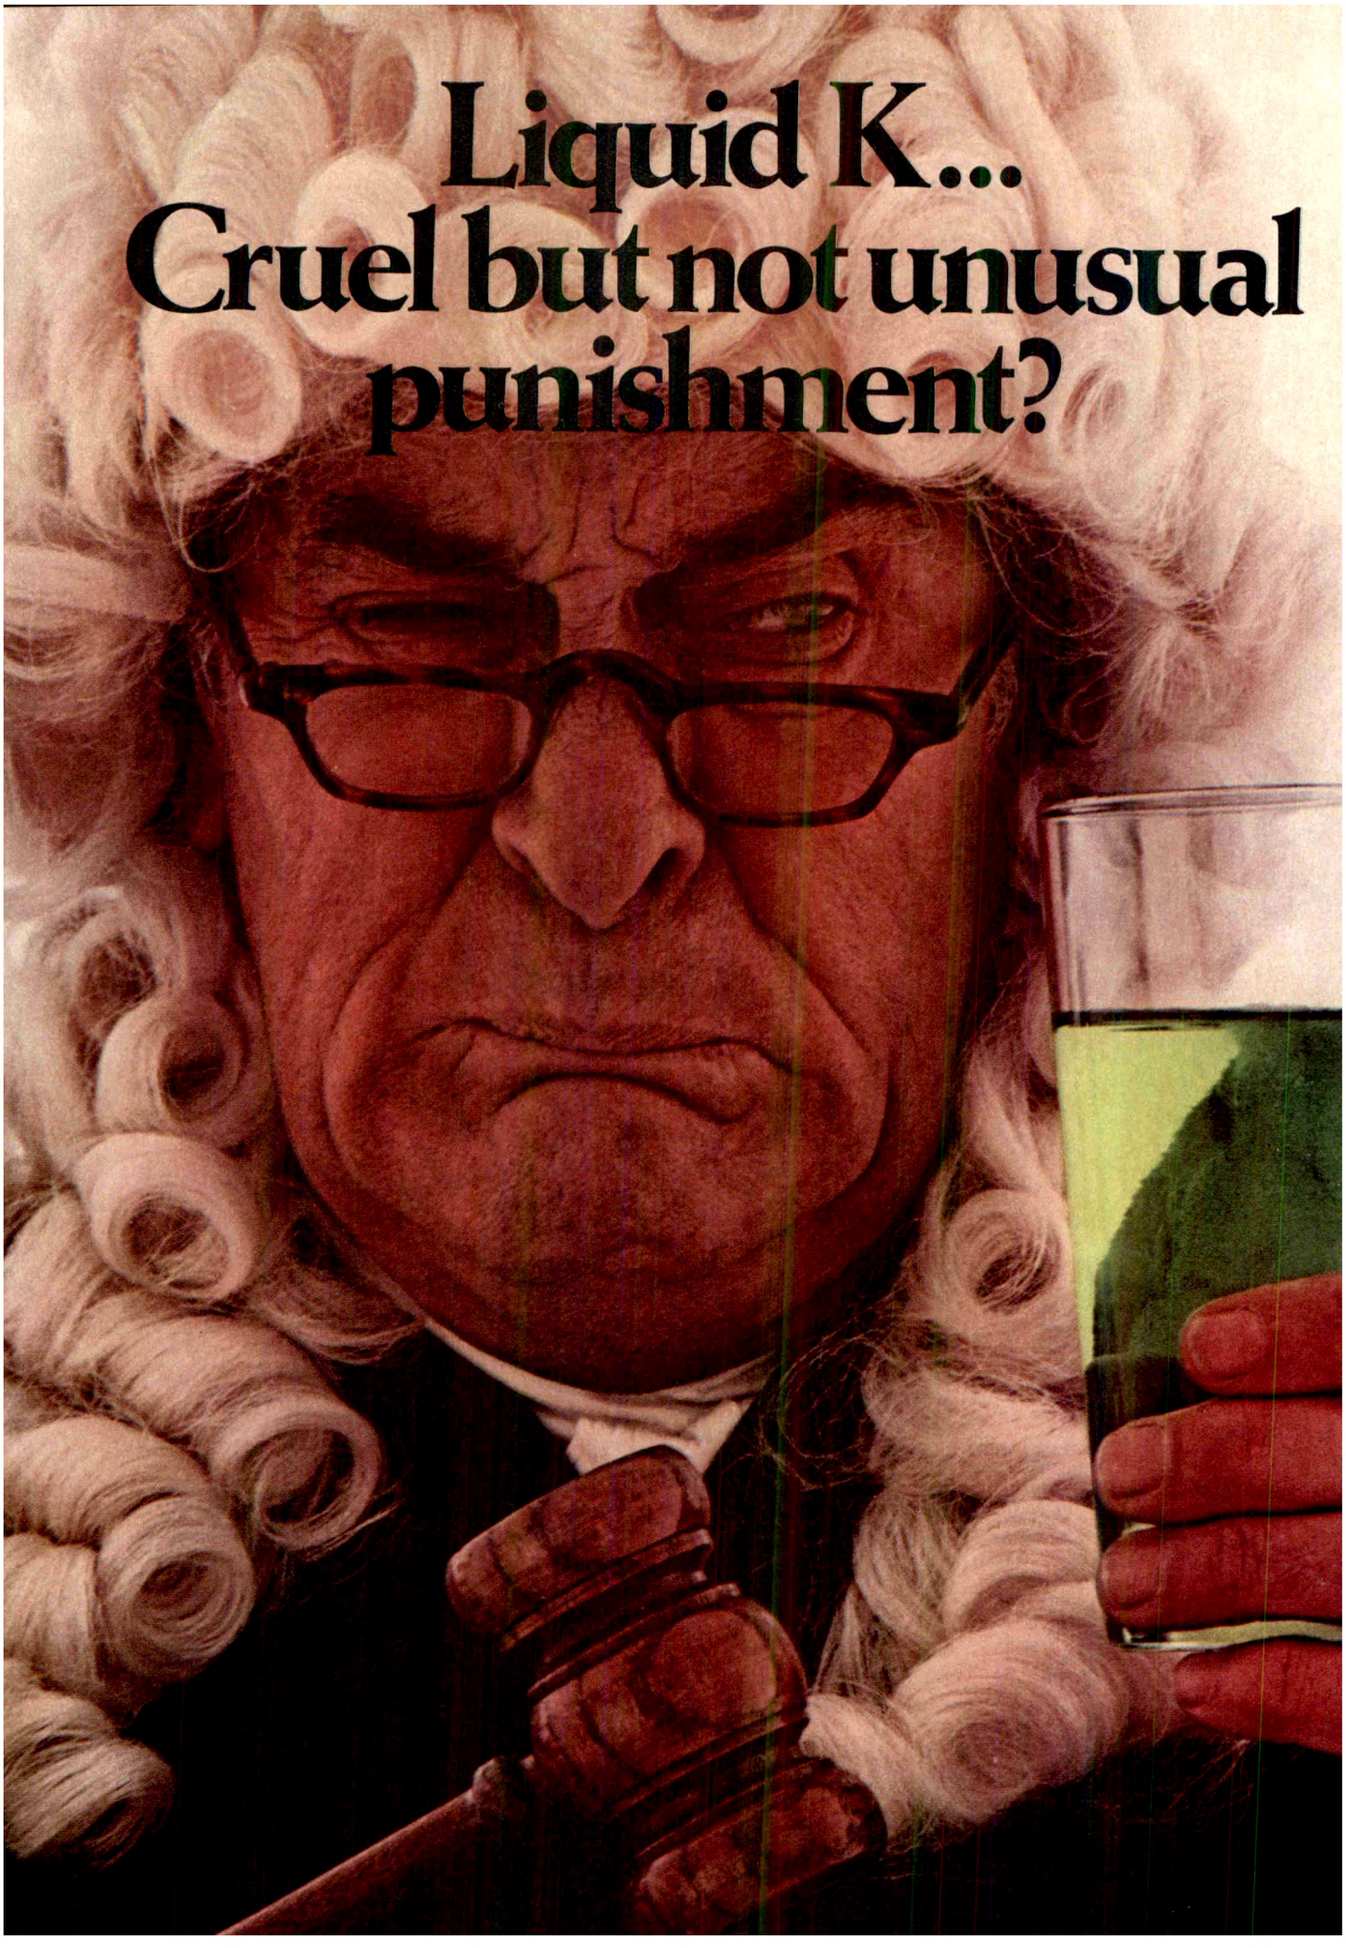
You know the Burdick EK-8 records a complete 12-lead ECG automatically... in less than 8 seconds.

That's impressive in a single-channel cardiograph.

But there's another important part to the EK-8 story.

The EK-8 was designed to save physician and staff time. And while it makes good sense to save time recording the ECG, think of the additional time-saving benefits when you can mount and file the ECG in less time than it takes to record the 12-lead tracing.

That's why the EK-8 fast mounting system is important to you. The answer is in our unique card and folder-format mounts. When the ECG is recorded, the technician takes the complete tracing, with each lead already clearly marked, and quickly positions it on the pressure-sensitive card or folder-format mount. No die-cutting. No pasting or taping. It's ready for filing. It can take less than a minute to record *and* mount the ECG.



The Burdick mounting system. Because the ECG isn't complete until the paperwork's done.

Find out how the EK-8 can increase your ECG productivity... from start to finish. Call or write **The Burdick Corporation, Milton, Wisconsin 53563.**

BURDICK

A concern for cardiac care

Liquid K...
Cruel but not unusual
punishment?

Slow-K®

CIBA 165

potassium chloride slow-release tablets 8 mEq

When compliance with liquid K supplements is a problem*

Accepted

A leading cardiology textbook clearly defines why Slow-K has become the accepted therapy for more and more patients who require a potassium supplement:

"All liquid potassium preparations are associated with some incidence of unpleasant side effects such as unpalatability, nausea, vomiting, abdominal cramps, and occasionally diarrhea."[1]

However, Slow-K "...appears to have greater patient acceptability than comparable doses of liquid potassium chloride compounds."[1]

Controlled

Slow-K provides controlled release of potassium into the gastrointestinal tract. One comparative study found that it caused less nausea, heartburn, and diarrhea than liquid KCl preparations.[2]

Economical

The cost of a day's therapy with Slow-K is minimal. With its excellent record of efficacy, safety, and patient acceptability, Slow-K is number one at any price.

*Slow-release potassium chloride tablets should be reserved for patients who cannot tolerate, refuse to take, or have compliance problems with liquid K preparations because of reports of GI ulceration and bleeding with slow-release KCl tablets (total number of GI lesions in both foreign countries and the United States remains less than one per 100,000 patient-years). The incidence of lesions with enteric-coated KCl tablets is 40-50 per 100.000 patient-years.

Used in over 4 million patients in the U.S. alone[3]... Slow-K

C I B A

SLOW-K®
potassium chloride slow-release tablets

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS
Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings): other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE
Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

Intermedics Pulse Generators

INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacemaking are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting with intractable, recurrent, congestive heart failure; cerebral or renal insufficiency; or recurrent, drug-resistant tachyarrhythmias who have been shown to benefit from temporary cardiac pacing are considered candidates for permanent cardiac pacemaking.

The indications for permanent pacing in the presence of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, mechanism of the arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias which impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. However, body rejection phenomena such as local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

CAUTION: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

NOTE: The CyberLith and the CyberLith Programmer are currently undergoing clinical evaluation.

Intermedics Inc.
Our business is life.™

The CyberLith programming system.

Reliable, safe, convenient. And available.

CyberLith... the most sophisticated programming system ever.

Reliable

The CyberLith all electronic programming system assures reliability by eliminating phantom or cross-programming. The use of accurate crystal oscillators ensures precision transmission of programming information.

Safe

The CyberLith programming safety features help avoid unnecessary cardiac rhythm disturbances. Further, it is not necessary to place the pulse generator in the asynchronous mode during the programming session. The safety features also allow automatic error identification, preventing transmission of incompatible programming commands.

Convenient

The CyberLith programming system is fast — all five parameters are programmed within 40 milliseconds.

Available

CyberLith pacing systems are available now! Pulse generators, programmers, leads, telemetry equipment, and patient transmitters and receivers.

As the pioneers of multi-parameter programmable pacing technology, Intermedics has maintained its role as the manufacturer of the most advanced systems. Our commitment is to keep in pace with your desire for excellence pacing therapy.

The CyberLith system is today's state-of-the-art. Get to know it. Fo more detailed information call or w the Intermedics marketing departm or contact your local Intermedics representative.

REPORTS ON THERAPY

855 Efficacy, Plasma Concentrations and Adverse Effects of A New Sustained Release Procainamide Preparation

ELSA-GRACE V. GIARDINA, PAUL E. FENSTER, J. THOMAS BIGGER, Jr., MICHAEL MAYERSOHN, DONALD PERRIER and FRANK I. MARCUS

Sustained release procainamide proved an effective antiarrhythmic agent as indicated by the greater than 90 percent suppression of ventricular premature depolarizations in 76 percent of 33 patients with this arrhythmia. This agent was also potent against complex forms of ventricular arrhythmias, including paired complexes, ventricular tachycardia and ventricular premature depolarizations with the R on T phenomenon. Adverse drug effects, which appeared early in 52 percent of the group, were minor and abated within 24 hours after administration of the drug was stopped. There was a relation between high procainamide and N-acetylprocainamide plasma concentrations and untoward drug effects. The steady plasma drug concentrations attained with the new formulation allow a longer dosing interval, which is a significant improvement over that of the conventional procainamide preparation.

863 Further Insights Into Digoxin-Quinidine Interaction: Lack of Correlation Between Serum Digoxin Concentration and Inotropic State of the Heart

PAUL D. HIRSH, HOWARD J. WEINER and ROBERT L. NORTH

The results of this digoxin-quinidine interaction study in nine healthy human subjects aged 26 to 31 years support the theory that quinidine displaces digoxin from tissue-binding sites and, more specifically, from cardiac-binding sites. A significant increase of 21 percent was observed in serum digoxin concentrations within 1 to 6 hours after a single oral quinidine dose administered 10 hours after the last digoxin dose. After four doses of quinidine were given over 24 hours, the serum digoxin concentration increased by 59 percent. Further research is needed to determine if this increase in serum digoxin concentration resulting from the digoxin-quinidine interaction is associated with an increased or decreased risk of digitalis toxicity and if the recommendation to reduce the maintenance digoxin dose when concomitant quinidine therapy is initiated is valid.

DIAGNOSTIC SHELF

869 Differentiation of Left Ventricular Pseudoaneurysm From True Aneurysm With Two Dimensional Echocardiography

ROBERT P. GATEWOOD, Jr. and NAVIN C. NANDA

This preliminary study indicates that real time two dimensional echocardiography is a useful and safe noninvasive method for differentiating a pseudoaneurysm from true aneurysm of the left ventricle. Pseudoaneurysm produces a bounded echo-free space with a narrow neck that communicates with the left ventricular cavity. The maximal internal width of this neck (O_{max}) of the aneurysmal sac is much smaller than the maximal parallel internal diameter (D_{max}); the ratio O_{max}/D_{max} never exceeded 0.5. In the true aneurysm the maximal internal width of the mouth (O_{max}) was nearly equal to or actually represented the maximal internal diameter (D_{max}); the ratio O_{max}/D_{max} ranged from 0.9 to 1.0.

879 Gallium-67 Citrate Scanning for Noninvasive Detection of Inflammation in Pericardial Diseases

JOHN B. O'CONNELL, JOHN A. ROBINSON, ROBERT E. HENKIN and ROLF M. GUNNAR

Therapy for acute nonspecific pericarditis not complicated by constriction or impending tamponade is controversial. The development of a noninvasive reproducible technique for detecting and assessing a pericardial inflammatory reaction is necessary before properly controlled clinical studies testing the efficacy of corticosteroids versus nonsteroid agents in nonbacterial pericardial inflammation can be completely interpreted. Data in four patients with acute pericarditis indicate that the inflammation-avid isotope, gallium-67 citrate, which localized in the cardiac silhouette of all, may provide the marker of inflammation and its resolution necessary for the success of such therapeutic studies.

continued on page A43

97.5% HOLTER DETECTION ACCURACY

HOLTER II/AUTOSCAN

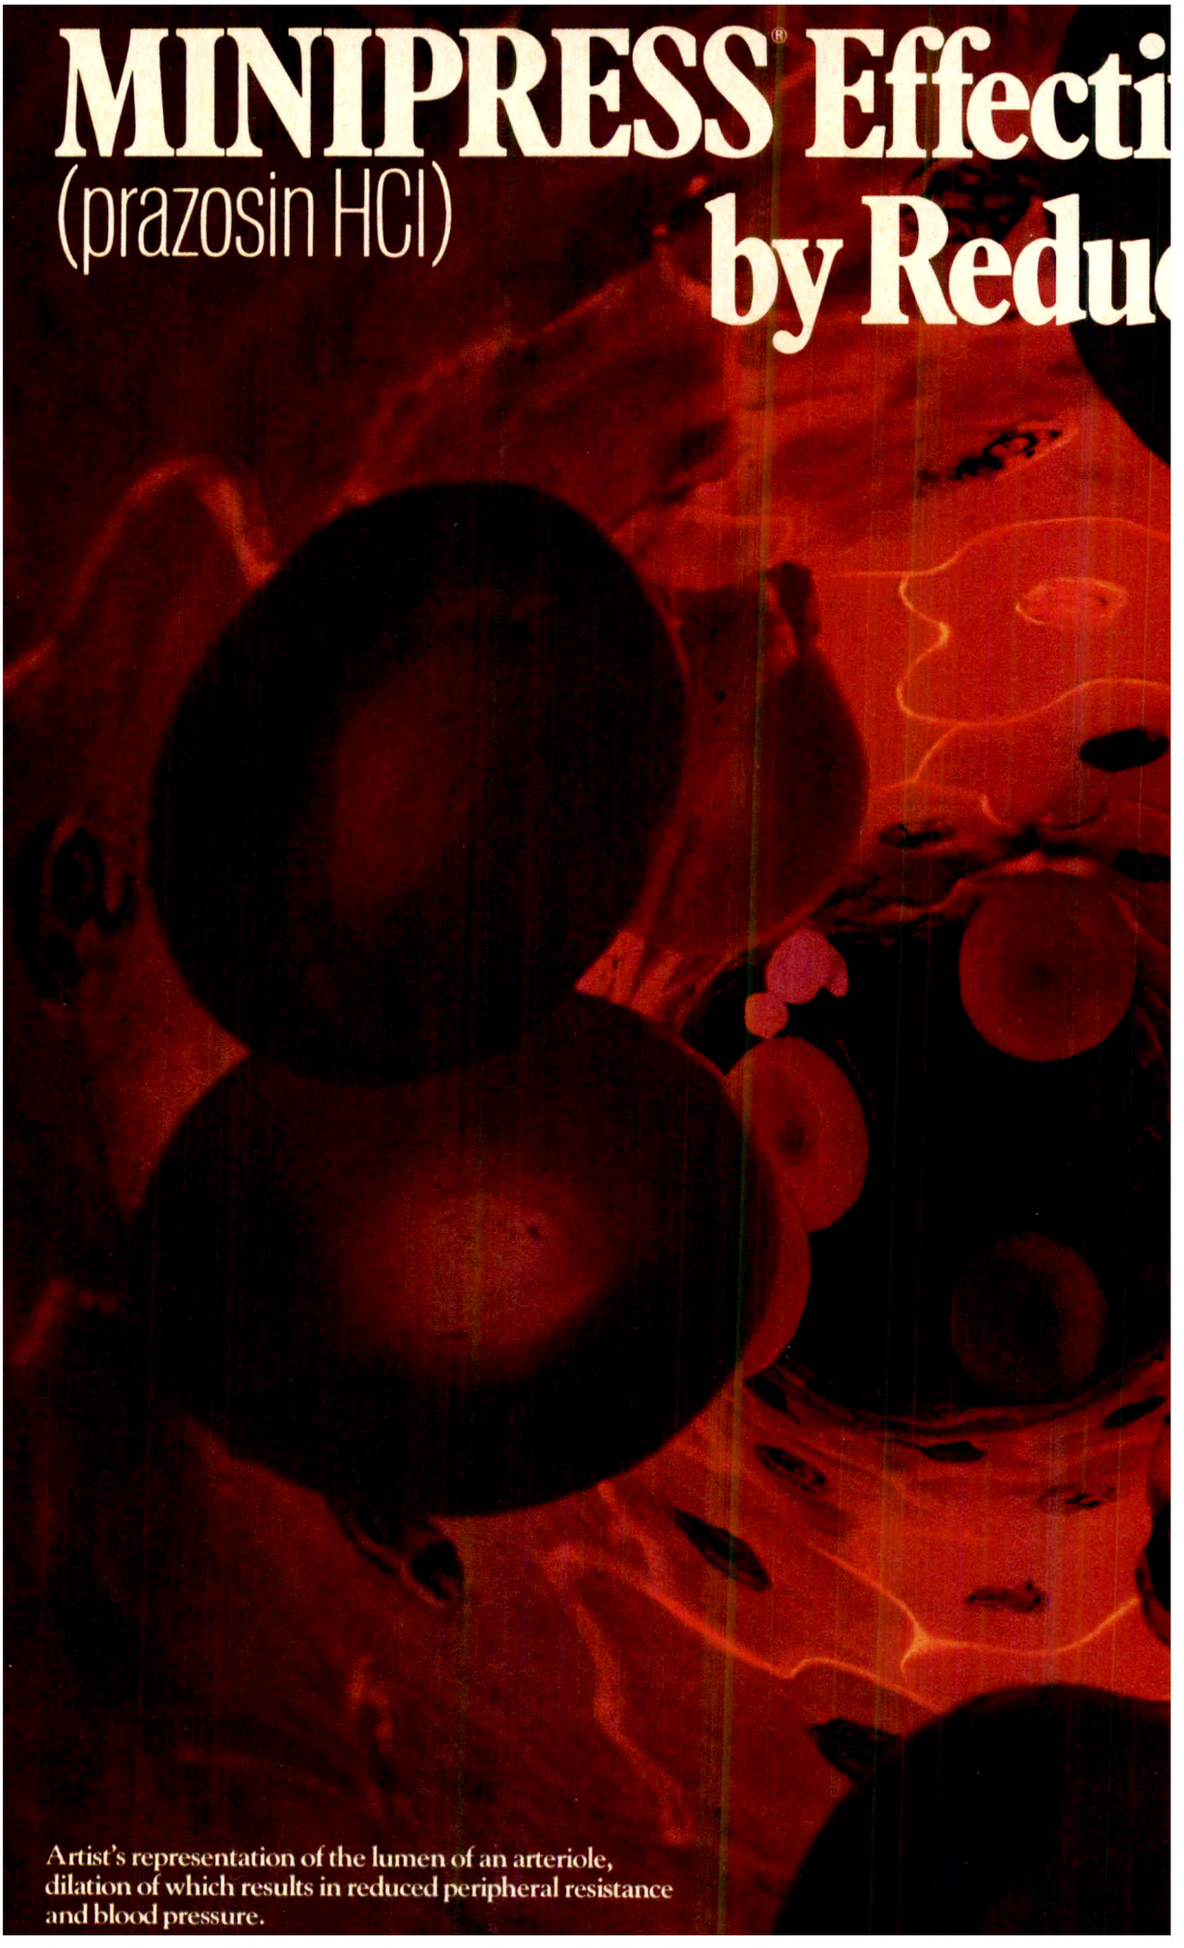
The Accuracy

Holter II/Autoscan is the ONLY Holter System that computer analyzes every ECG complex on a "real time", beat-by-beat basis, DURING the actual patient monitoring period. Every ECG complex is compared to that patient's averaged updated "normal" complex for changes in rate, rhythm, morphology and signal quality (artifact). Since this computer analysis is performed at "real-time" rather than 60, 120, 240, or 480 times normal, Holter II/Autoscan has achieved a level of detection accuracy and ease of operation not possible with any other Holter system. Clinical Studies* have demonstrated an average of 97.5% quantitative detection accuracy and 100% qualitative detection accuracy. And, since the tape you receive from the patient is completely "pre-analyzed", only 6 minutes of operator time is required to process the tape.

The Challenge

Holter manufacturers' advertising often contains claims of increased accuracy of their respective systems. However, data to support these claims are rarely, if ever, provided. Now IMC has taken the lead with the only validated Holter system on the market.

WE CHALLENGE YOU TO COMPARE HOLTER II/AUTOSCAN:



- **TO YOUR PRESENT HOLTER SYSTEM**
- **TO ANY HOLTER SYSTEM YOU ARE CONSIDERING FOR PURCHASE**

If you want to know what you have been (or will be) missing: stop by IMC's booth at the AHA Meeting or check the system you want to compare on this ad and send it along with your name and address to IMC, (or call our toll free phone number). We will provide you a patient Holter tape compatible with the system you indicate, a hand count of every abnormal complex classified by type of anomaly, and the detection accuracy of the Holter II/Autoscan System for that tape. We know you'll find the results to be enlightening!

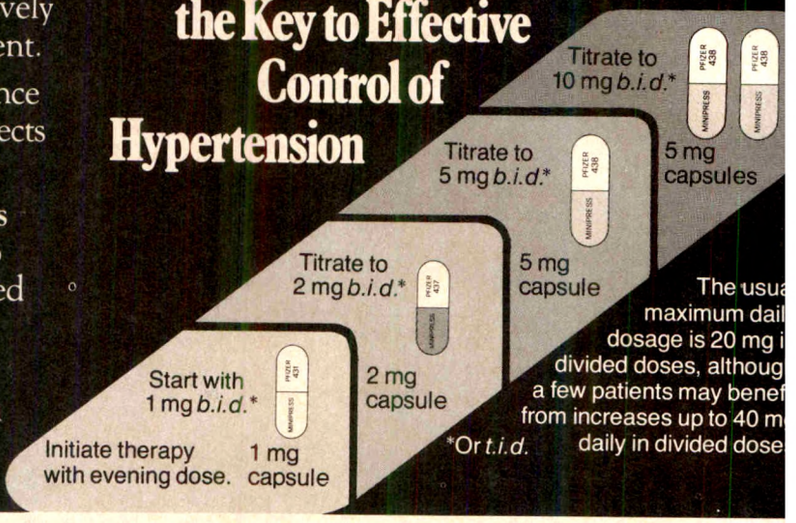
MINIPRESS®



(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Please see Brief Summary on last page.

© 1980 Pfizer Inc.

MINIPRESS®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

- **Effectively lowers elevated blood pressure by reducing peripheral resistance.**
- **Maintains cardiac output** which allows patients to maintain an active life style.
- **Maintains renal blood flow and glomerular filtration rate** so it can be used effectively even in patients with renal impairment.
- **Not a CNS agent** so patients experience few of the troublesome CNS side effects that impair their quality of life.
- **Cardiovascular response to exercise is preserved** so patients are less likely to experience the fatigue often associated with beta-blocker therapy.
- **A small percentage of patients** have experienced orthostatic hypotension and syncope.

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, incontinence, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy, however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

CASE REPORTS

885 Congenital Hypoplasia of Portions of Both Right and Left Ventricular Myocardial Walls. Clinical and Necropsy Observations in Two Patients With Parchment Heart Syndrome

BRUCE F. WALLER, ELDON R. SMITH, BRIAN D. BLACKBOURNE, FELIX P. ARCE, NELLIE N. SARKAR and WILLIAM C. ROBERTS

Clinical and morphologic data in 2 patients with congenital hypoplasia of portions of both right and left ventricular free walls in the absence of associated coronary or valvular heart disease and from 22 necropsy patients in a review of the pertinent literature are presented. Nearly half of these patients died of congestive heart failure in the 1st year of life and the other half reached adulthood with or without manifestations of cardiac dysfunction. The differential diagnosis of congenital hypoplasia of the right ventricular myocardium includes Ebstein's anomaly of the tricuspid valve, idiopathic dilated cardiomyopathy and pulmonary or tricuspid valve atresia. The echocardiogram is useful in distinguishing congenital hypoplasia of the right ventricular myocardium from Ebstein's anomaly by the presence of a dilated right ventricular cavity, delayed tricuspid valve closure, and diastolic opening of the pulmonary valve.

892 Biventricular Hypoplasia With Myocardial Fiber Hypertrophy and Disarray

WILLIAM C. LITTLE, H. CECIL COGHLAN and JACK C. GEER

Postmortem examination of this 25 year old woman with effort intolerance and systemic venous congestion since childhood confirmed an unusual case of cardiac biventricular hypoplasia and dysplasia with fiber hypertrophy and disarray that resulted in restrictive ventricular dysfunction, impaired cardiac output, atrioventricular valve incompetence and marked enlargement of the atria. This condition differs from Uhl's anomaly in that this patient's right ventricle, although quite thin in some areas, contained functioning myocardium and did contract. The patient died after valve replacement surgery.

905 American College of Cardiology News

THE TRENDSETTER™ — The top-of-the-line scanner for integrated ECG, blood pressure and pacemaker evaluation, together with comprehensive alphanumeric/graphic summaries.

VIS-U-SCAN™ — The high-speed system that puts 24 hours of ECG in your hands in three minutes flat without missing a beat.

SMART SCANNERS, SMART VALUES

There's a Del Mar Avionics ECG scanner that satisfies your most exacting requirements — in the hospital or in your office. And a worldwide network of se centers assures fast, professional response when you need it, where you need it.

An outstanding Education and Training staff rounds out our commitment excellence. Training courses extend the skills and knowledge of your staff in the cation of ECG principles to Holter System data analysis.

Our full line of smart scanners coupled with the extra services only a lead can provide, makes your investment in a Del Mar Avionics system a smart move your local representative today.

Holter scanning system handles the workload right in your office. Two channels of data with memory-scope display make it fast, flexible and easy-to-use.

THE EVALUATOR,™ NEW! — The middle-of-the-line Holter ECG scanner — microprocessor-controlled, features "smart" arrhythmia analyzer.

Three New Reasons Why Daig/Medcor Is

And we're proud to make that statement. We're backing it up with the addition of three new pacemakers that are designed to meet or surpass what you are now implanting in terms of capability, performance, and reliability. The same kind of reliability we've built into every Daig/Medcor pacemaker.*

Why three at once? To be certain that you have a reliable, well-engineered pacemaker to suit individual patient needs. It's all part of our commitment to provide you with the latest in pacing technology.

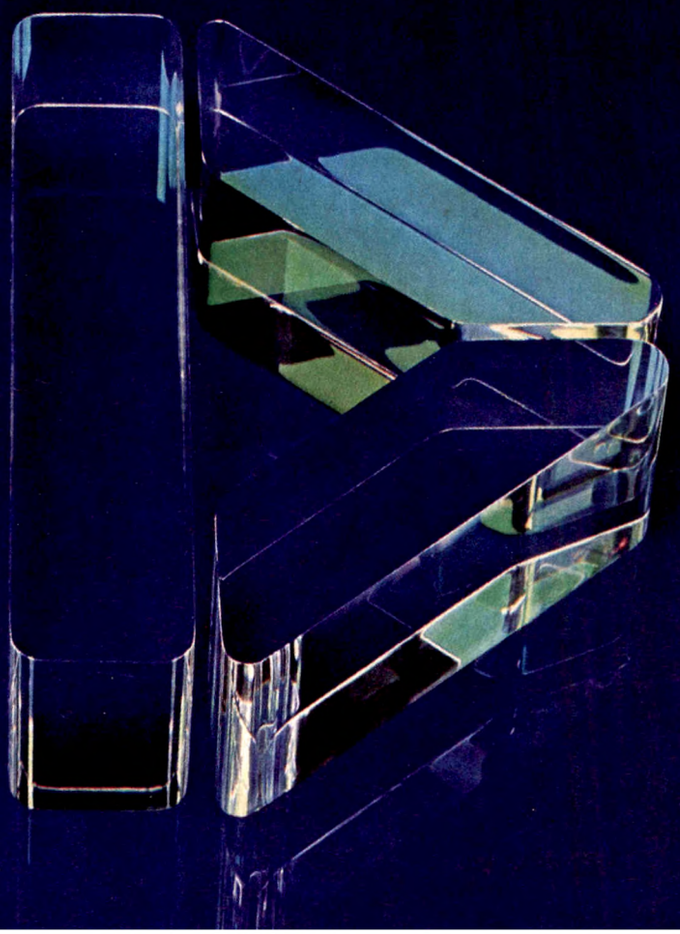
* Ask for our current reliability study on Daig/Medcor's pacemaker technology that is based on nearly 100 million hours of pacing.

When your patient needs a multi-programmable pacemaker.

Our new Lithicron 515 allows alterations of rate, pulse width, output, sensitivity, refractory, mode, and features telemetry confirmation . . . and all in the confines of an 11 mm thin configuration.

When your patient needs a simple demand pacemaker.

Our new Lithicron III 411 offers the benefits of proven circuitry and reliable lithium power source, backed by eight years of clinical history. All designed in a unit that is our smallest model yet.



When your patient needs atrially associated pacing

Our new VISA pacemakers, Models 520/620 are two of the most advanced pacemakers on the market, giving the patient complete physiological control of rate in order to adapt to periods of rest and exertion. Simulating normal cardiac activity, P-wave synchronous pacing greatly improves cardiac performance.

The Answer.

se three new models are part aig/Medcor's complete line ulse generators. We are cated to provide innovations mple demand, multi- rammable and now nchronous pacing. WHEN YOU SUSPECT OR DETEC VENOUS THROMBOSIS...

Thromboembolism: a high risk among patients with one or more of these factors...

Advanced age
Fractures of lower limb
Hip surgery
Pelvic or abdominal surgery with extensive dissection
Previous venous thromboembolism
Congestive cardiac failure
Cancer surgery
Obesity
Varicose vein surgery

Incidence of venous thrombosis or abnormal scans as shown by ^{125}I-fibrinogen screening in selected high-risk medical-surgical patients

Category	Incidence
Elective surgery	
Major abdominal thoracic/gynecologic	11-65%[1,2]
Retropubic prostatectomy	28-50%[1,2]
Transurethral prostatectomy	4%[1,2]
Emergency surgery	
Hip fracture	48-74%[1,2]
Childbirth	3%[1,2]
Medical	
Myocardial infarction	23-38%[1,2]
Stroke	60%[1]

ORAL ANTICOAGULATION:
Often indicated to lower the risk of thromboembolic complications.

References: 1. Hirsh J, Gallus AS. ^{125}I-labeled fibrinogen scanning. Use in the diagnosis of venous thrombosis. *JAMA* 233:970-973, 1975. **2.** Kakkar VV. Prophylactic and therapeutic use. *Postgrad Med* 55:211-217, Jan 1974.

*For selected patients who have had a large infarct, a history of previous infarction or angina, severe hypotension or shock, chronic atrial fibrillation, congestive heart failure, past history of venous thrombosis or embolism or complications requiring a prolonged period in bed.

The oral anticoagulant of choice:

Tablets
COUMADIN®
crystalline warfarin sodium

singled out by more than 20 years of experience

Effective prophylaxis and treatment of venous thrombosis
Effective prophylaxis and treatment of pulmonary embolism
Effective treatment of atrial fibrillation with embolization
Effective adjunctive treatment of coronary occlusion

Initiation of therapy

Induction – 40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response.

- dosage must be individualized according to patient's prothrombin time
- frequent laboratory monitoring is recommended
- determine prothrombin time daily until results fall within the therapeutic range – 1.5 to 2.5 times normal
- afterwards, prothrombin time must be determined periodically to monitor the patient's course

Maintenance of anticoagulation

- 2-10 mg, for most patients (scored tablets allow flexibility and accurate titration)
- dose and interval should be adjusted according to the individual patient's prothrombin time response

Duration of anticoagulation

- should be individualized for each patient
- in general, should be continued until danger of thrombosis and embolism has passed

Recommendations of prominent clinicians on duration of therapy

in myocardial infarction[3,4*]	1-3 years* (reevaluate at least every 6 months)
in pulmonary embolism[4,5]	6 weeks-6 months
in deep vein thrombosis[4,5]	6 weeks-6 months

COUMADIN® Tablets
for long- and short-term oral anticoagulation...
crystalline warfarin sodium, U.S.P.*

DESCRIPTION COUMADIN (crystalline warfarin sodium), a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of warfarin sodium virtually eliminates trace impurities present in amorphous warfarin sodium, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN (crystalline warfarin sodium) is therapeutically equivalent to amorphous warfarin sodium.

ACTIONS COUMADIN and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy—COUMADIN is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1)central nervous system; (2)eye; (3)traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1)gastrointestinal, genitourinary or respiratory tracts, (2)cerebrovascular hemorrhage; (3)aneurysms—cerebral, dissecting aorta; (4)pericarditis and pericardial effusions; (5)subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis, or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** major regional, lumbar block anesthesia and malignant hypertension.

WARNINGS Warfarin sodium is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN are given together, a period of at least 5 hours should elapse after the last intravenous dose and 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when warfarin sodium is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Lactation—coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, severe allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN.

Concurrent use of anticoagulants with streptokinase or urokinase is not recommended and may be hazardous. (Please note recommendations accompanying these preparations.)

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol; aminosalicylic acid; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cimetidine; cinchophen; clofibrate; COUMADIN (crystalline warfarin sodium) overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methyldopa; methylphenidate; metronidazole; monoamine oxidase inhibitors; nalidixic acid; oxolinic acid; oxyphenbutazone; phenylbutazone; phenyramidol; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates; sulfinpyrazone; sulfonamides, long acting; thyroid drugs; tolbutamide; triclofos sodium; trimethoprim/sulfamethoxazole; unreliable prothrombin time determinations.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus; edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN underdosage; diet high in vitamin K (vegetables, fish, fish oil, onions); diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

*Present as crystalline sodium warfarin isopropanol clathrate.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (diphenylhydantoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN (crystalline warfarin sodium) include:

1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer, etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and a reaction consisting of hemorrhagic infarction and necrosis of the skin.

3. Priapism has been associated with anticoagulant administration, however, a causal relationship has not been established.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN patient aids are available to physicians on request.

The administration and dosage of COUMADIN must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic anticoagulation are 1½ to 2½ times the normal prothrombin time (e.g. 18 to 30 seconds, with a control of 12 seconds).

Induction—40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response. The basis for the no-loading dose regimen is that the depression of Factors II, IX, and X are not accelerated by the administration of a loading dose.

Maintenance—Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy—The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery—The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN (crystalline warfarin sodium) be adjusted to maintain the prothrombin time at approximately 1½ to 2½ times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN with Heparin—Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in emergency situations to administer sodium heparin initially along with COUMADIN. The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe. It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, at least 5 hours after the last intravenous injection or 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN (crystalline warfarin sodium), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN (crystalline warfarin sodium). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous warfarin sodium lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution.

50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg. pH is adjusted with sodium hydroxide; accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

LANOXIN®
(DIGOXIN)
TABLETS
0.125 mg Scored (yellow), I.D. Imprint Y3B
0.25 mg Scored (white), I.D. Imprint X3A
0.5 mg Scored (green), I.D. Imprint T9A

LANOXIN®
(DIGOXIN)
ELIXIR PEDIATRIC
50 mcg (0.05 mg) per cc

INDICATIONS:
1. **Congestive heart failure:** Congestive heart failure, all degrees, is the primary indication. The increased cardiac output due to digoxin results in diuresis and general amelioration of the disturbances characteristic of right (venous congestion, edema) and left (dyspnea, orthopnea, cardiac asthma) heart failure.

Digoxin, generally, is most effective in "low output" failure and less effective in "high output" (bronchopulmonary insufficiency, infection, hyperthyroidism) heart failure.

Digoxin should be continued after heart failure is abolished unless some known precipitating factor is corrected.

2. **Atrial fibrillation:** Atrial fibrillation, especially when the ventricular rate is elevated. Digoxin rapidly reduces ventricular rates and eliminates the pulse deficit. Palpitation, precordial distress or weakness are relieved and any concomitant congestive failure ameliorated. Digoxin should be continued in doses necessary to maintain the desired ventricular rate and other clinical effects.

3. **Atrial flutter:** Digoxin slows the heart and regular sinus rhythm may appear. Frequently the flutter is converted to atrial fibrillation with a slow ventricular rate. Stopping digoxin at this point may be followed by restoration of sinus rhythm, especially if the flutter was of the paroxysmal type. It is preferable, however, to continue digoxin if failure ensues or if atrial flutter is a frequent occurrence.

4. **Paroxysmal atrial tachycardia:** Oral digoxin may be used, especially if the condition is resistant to lesser measures. Depending on the urgency, a more rapid acting parenteral preparation may be preferable to initiate digitalization, although if heart failure has ensued or paroxysms recur frequently, digoxin should be maintained by oral administration.

Digoxin is not indicated in sinus tachycardia unless due to heart failure.

5. **Cardiogenic shock:** The drug is often employed, especially when the condition is accompanied by pulmonary edema. Digoxin seems to affect adversely shock due to septicemia from gram-negative bacteria.

CONTRAINDICATIONS: The presence of toxic effects (see ADVERSE REACTIONS section) induced by any digitalis preparation is a contraindication to all of the glycosides.

Allergy, though rare, does occur. It may not extend to all preparations, and another may be tried.

Ventricular fibrillation.

WARNINGS:

> Digitalis alone or with other drugs has been promoted for use in the treatment of obesity. This use of digoxin or other digitalis glycosides is unwarranted. Moreover, since they may cause potentially fatal arrhythmias or other adverse effects, the use of these drugs in the treatment of obesity is dangerous.

Many of the arrhythmias for which digoxin is advised closely resemble those reflecting digoxin intoxication. If the possibility of digoxin intoxication cannot be excluded, cardiac glycosides should be temporarily withheld if permitted by the clinical situation.

The patient with congestive heart failure may complain of nausea and vomiting. These symptoms may also be indications of digoxin intoxication. A clinical determination of the cause of these symptoms must be attempted before further drug administration.

Patients with renal insufficiency require smaller than usual doses of digoxin. Newborn infants display considerable variability in their tolerance to digoxin, depending on their degree of maturity.

Premature and immature infants are particularly sensitive, and dosage must be reduced and digitalization should be even more individualized and cautiously approached than in more mature infants. Impaired renal function must also be carefully taken into consideration.

Congestive heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. A relatively low total dose administered in divided doses and concomitant use of antihypertensive drugs has been recommended. ECG monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with idiopathic hypertrophic subaortic stenosis must be managed extremely carefully. Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with rheumatic carditis, especially when severe, are unusually sensitive to digoxin and prone to disturbances of rhythm. If heart failure develops, digitalization may be initiated with relatively low doses; then it can be cautiously increased until a beneficial effect is obtained. If a therapeutic trial does not result in improvement, the drug should be considered ineffective and be discontinued.

Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS: Atrial arrhythmias associated with hypermetabolic states are particularly resistant to digoxin treatment. Care must be taken to avoid digoxin toxicity if digoxin is used to help the arrhythmia.

Digoxin is not indicated for the treatment of ventricular tachycardia unless congestive heart failure supervenes after a protracted episode not itself due to digoxin.

Potassium depletion sensitizes the myocardium to digoxin and toxicity may develop even with usual dosage. Hypokalemia may also alter the rate of onset and intensity of the positive inotropic effect of digoxin. Therefore, it is desirable to maintain normal serum potassium levels in patients being treated with digoxin.

Potassium wastage may result from diuretic or corticosteroid therapy, hemodialysis, and from suction of gastrointestinal secretions. It may accompany malnutrition, diarrhea, prolonged vomiting, old age, and long-standing congestive heart failure. In general, rapid changes in serum potassium or other electrolytes are to be avoided, and intravenous treatment with potassium should be reserved only for special circumstances as described below (see TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGES section).

Patients with acute myocardial infarction, severe pulmonary disease, or far advanced heart failure may be more sensitive to digoxin and more prone to disturbances of rhythm.

Calcium affects contractility and excitability of the heart in a manner similar to that of digoxin. Calcium may produce serious arrhythmias in digitalized patients.

In myxedema, the digoxin requirements are less because excretion rate is decreased and blood levels are significantly higher.

In incomplete A-V block, especially in patients subject to Stokes-Adams attacks, advanced or complete heart block may develop if digoxin is given. Heart failure in these patients can usually be controlled by other measures and by increasing the heart rate.

Patients with chronic constrictive pericarditis may respond unfavorably to digoxin.

Patients with idiopathic hypertrophic subaortic stenosis must be managed extremely carefully. Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Renal insufficiency delays the excretion of digoxin and dosage must be adjusted accordingly in patients with renal disease. Note: This applies also to potassium administration should it become necessary.

Electrical conversion of arrhythmias may require reduction of digoxin dosage.

Dosage must be carefully titrated and differences in the bioavailability of parenteral preparations, elixirs, and tablets should be taken into account when switching patients from one preparation to another.

Electrocardiographic monitoring may be necessary to avoid intoxication.

Premonitory signs of toxicity in the newborn are undue slowing of the sinus rate, sinoatrial arrest, and prolongation of PR interval.

ADVERSE REACTIONS:
Gynecomastia: Uncommon.

Overdose or toxic effects in adults:
Gastrointestinal: Anorexia, nausea, vomiting, diarrhea are the most common early symptoms of overdosages in the adult (but rarely conspicuous in infants). Uncontrolled heart failure may also produce such symptoms.

Central nervous system: Visual disturbances (blurred vision, yellow vision), headache, weakness, apathy.

Cardiac disturbances (arrhythmias): Ventricular premature beats are the most common, except in infants and young children. Paroxysmal and nonparoxysmal nodal rhythms, atrioventricular (interference) dissociation and paroxysmal atrial tachycardia (PAT) with block are also common arrhythmias due to digoxin overdosage.

Conduction disturbances: Excessive slowing of the pulse is a clinical sign of digoxin overdosage. Atrioventricular block of increasing degree may proceed to complete heart block. Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac toxic disturbances. Digoxin may also induce other changes (as of the ST segment), but these provide no measure of the degree of digitalization.

Overdose or toxic effects in children:
Toxic signs differ from the adult in a number of respects. Cardiac arrhythmias are the more reliable and frequent signs of toxicity.

Vomiting and diarrhea, neurologic and visual disturbances are rare as initial signs.

Premature ventricular systoles are rarely seen; nodal and atrial systoles are more frequent.

Atrial arrhythmias, atrial ectopic rhythms, and paroxysmal atrial tachycardia with A-V block particularly are more common manifestations of toxicity in children.

Ventricular arrhythmias are rare.

TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE: Digoxin should be discontinued until all signs of toxicity are abolished. Discontinuation may be all that is necessary if toxic manifestations are not severe and appear after the time for peak effect of the drug.

Potassium salts are commonly used. Potassium chloride in divided oral doses totaling 4-6 grams for adults (see PEDIATRIC INFORMATION section for pediatric dosage) may be given provided renal function is adequate.

When correction of the arrhythmia is urgent and the serum potassium level is low or normal, potassium should be administered intravenously in a solution of 5 percent dextrose in water. A total of 40-100 milliequivalents (30 milliequivalents per 500 milliliters) is given at the rate of 20 milliequivalents per hour unless limited by pain due to local irritation.

Additional amounts may be given if the arrhythmia is uncontrolled and the potassium well tolerated.

Continuous electrocardiographic monitoring should be performed to watch for any evidence of potassium toxicity, e.g., peaking of T waves, and to observe the effect on the arrhythmia so that the infusion may be promptly stopped when the desired effect is achieved.

Caution: Potassium should not be used and may be dangerous for severe or complete heart block due to digoxin and not related to any tachycardia.

Other agents that have been approved for the treatment of digoxin intoxication include procainamide, lidocaine, and propranolol.

Pediatric Information: (See adult section for other recommendations for the treatment of arrhythmias produced by overdosages and for additional recommendations and cautions regarding the use of potassium.) Potassium preparations may be given orally in divided doses totaling 1-1.5 milliequivalents/kilogram (1 gram K contains 13.4 milliequivalents). When correction of the arrhythmia is urgent, approximately 0.5 milliequivalents/kilogram of potassium per hour may be given, with careful electrocardiographic monitoring, as a solution of 20 milliequivalents or less for 500 milliliters in 5 percent dextrose in water. The total dose should generally not exceed 2 milliequivalents of potassium/kilogram.

DOSAGE AND ADMINISTRATION: Oral digoxin is administered slowly or rapidly as required until the desired therapeutic effect is obtained without symptoms of overdosage. The amount can be predicted approximately from the lean body mass of the patient with allowances made for excretion during the time taken to induce digitalization.

Subsequent maintenance dosage is also determined tentatively by the amount necessary to sustain the desired therapeutic effect.

Recommended dosages are practical average figures that may require considerable modification as dictated by individual sensitivity or associated conditions. Diminished renal function is the most important factor requiring modification of recommended or average doses. (See WARNINGS and PRECAUTIONS sections.)

The average amount of digoxin that patients must accumulate to be digitalized with digoxin tablets is 1.0-1.5 milligrams. Digitalization may be accomplished by any of several approaches that vary in dosage and frequency of administration, but reach the same endpoint in terms of total amount accumulated.

In previously undigitalized patients, a single loading dose of 0.5-0.75 milligram orally usually produces a detectable effect in 1-2 hours that becomes maximal in 6-8 hours. Additional doses of 0.25-0.5 milligram may be given cautiously at 6-8 hour intervals to full digitalization.

In previously undigitalized patients, institution of daily maintenance therapy (0.125-0.5 milligram, see next paragraph) without a loading dose results in development of steady-state plateau concentrations in about 7 days in patients with normal renal function.

The average daily oral maintenance dose is 0.125-0.5 milligram, usually 0.25 milligram. In the elderly patient, 0.125-0.25 milligram should be considered the average maintenance dose.

In patients with renal impairment, digoxin excretion is impaired and serum half-life is prolonged. Digitalizing and maintenance doses are lower than those recommended for patients with normal renal functions. Signs of digoxin toxicity develop sooner in patients with renal impairment, and it takes longer for toxic signs and symptoms to disappear. Because of the prolonged half-life, a longer period of time is required to achieve an initial or new steady-state plateau in patients with renal impairment than in patients with normal renal function.

It cannot be overemphasized that the values given are averages and substantial individual variation can be expected.

Children: Digitalization must be individualized. Generally, premature and immature infants are particularly sensitive, requiring reduced dosage that must be determined by careful titration.

Oral Dosage. Beyond the immediate newborn period, children require proportionally greater doses than adults on the basis of body weight or surface area. The recommended oral digitalizing dosages in children with normal renal function are:

Newborn infants (normal), up to 1 month, require 40-60 micrograms (mcg)/kilogram.
Infants, 1 month to 2 years, require approximately 60-80 micrograms (mcg)/kilogram.
Children, 2 years to 10 years, require 40-60 micrograms (mcg)/kilogram.
Children, over 10 years of age, require adult dosages in proportion to their body weight.
Maintenance therapy is 20-30 percent of the digitalizing dose administered each day.

Long term use of digoxin is indicated in almost all infants who have been digitalized for acute congestive heart failure unless the cause is transient. Many favor maintaining digoxin until at least 2 years of age in all infants with paroxysmal atrial tachycardia or in those who show either definite or latent failure.

Many children with severe inoperable congenital defects need digoxin throughout childhood and often for life.

CLINICAL STUDIES

Calcific Deposits in Porcine Bioprostheses: Structure and Pathogenesis

VICTOR J. FERRANS, MD, PhD

Stanford, California

Gross, histologic and ultrastructural studies were made of 14 porcine valve bioprostheses that were found to contain calcific deposits at the time of removal either at reoperation (13 patients) or at necropsy (1 patient). Eleven bioprostheses had been in the mitral position, 1 in the aortic, 1 in the tricuspid and 1 in a pulmonary conduit. The ages of the patients at the time of implantation ranged from 2.5 to 65 years (average 32), and the bioprostheses had been in place from 3 to 94 months (average 39). Analysis of these 14 bioprostheses and review of reports concerning 37 other calcified porcine bioprostheses suggest the following conclusions: (1) Calcific deposits occur commonly in bioprostheses implanted in patients of all ages, but are more likely to become severe and clinically significant in children and in young adults than in older patients. (2) Calcific deposits can lead to prosthetic valve stenosis, because they can limit the mobility of the cusps; however, they can also be associated with prosthetic valve regurgitation. (3) Metabolic disorders that could contribute to bioprosthetic calcification are not identifiable in most patients having calcified prosthetic tissue valves. (4) The two main sites of deposition of calcium phosphate in porcine valve bioprostheses are the connective tissue in the cusps, particularly in the spongiosa, and small thrombi on the surfaces. (5) Calcification of connective tissue first involves the collagen fibrils; calcification of thrombi involves the mitochondria in platelets and leukocytes trapped in the mesh of fibrin. From these two sites, calcific deposits can grow and spread into other areas of the cusps.

A large majority of patients undergoing cardiac valve replacement with glutaraldehyde-treated porcine bioprostheses follow a clinically satisfactory course for the first 5 years after operation. Nevertheless, clinical and morphologic studies have documented certain complications leading to malfunction of porcine bioprostheses, mainly cuspal infection, perforation and calcification. Previous reports from our laboratory[1–3] have described gross, histologic and ultrastructural alterations developing in perforated or infected porcine bioprostheses. Calcification of porcine bioprostheses received little attention until recently, when isolated case reports[4–20] emphasized its occurrence, particularly in children and young adults. Although this complication may lead to a reduction in the mo-

bility of the cusps and to bioprosthetic stenosis or regurgitation, detailed studies have not been made of the precise location, structure and pathogenesis of calcific deposits in porcine bioprostheses. This study presents morphologic observations on 14 porcine bioprostheses that were found to contain calcific deposits when removed after being in place from 3 to 94 months.

Methods

Patients (Table I)

The 14 patients had calcific deposits in the cusps of the porcine bioprostheses manifested on either gross or microscopic examination. Seven patients had been included in previous clinical reports.[1,2,16,19,21,22] The patients, six boys or men and eight girls or women, ranged in age from 2.5 to 65 years (mean 32) at the time of bioprosthetic implantation.

Six patients had rheumatic heart disease, six had congenital heart disease, one had infective endocarditis and one had pure mitral regurgitation of uncertain origin. Twelve patients underwent single valve replacement by a porcine bioprosthesis: nine had mitral valve replacement, one aortic valve replacement, one tricuspid valve replacement and one pulmonary valve replacement. The tricuspid valve was replaced in one patient with transposition of the great vessels; thus, it functioned as a systemic atrioventricular valve and hereafter will be considered as a "mitral" replacement. The pulmonary valve was replaced by a Hancock conduit in a patient with pulmonary valve atresia and ventricular septal defect. Two patients underwent replacement of both the mitral and the tricuspid valve: Patient 13 had severe stenosis of both natural valves; both implanted porcine bioprostheses eventually became regurgitant and had to be replaced; however, only the bioprosthesis in the tricuspid position became calcified. Therefore, the mitral bioprosthesis in this patient is not included in the study. Patient 8 had pure mitral and tricuspid regurgitation resulting from infective endocarditis; after double valve replacement, a new episode of infective endocarditis developed and the porcine bioprosthesis in the mitral position was removed. The bioprosthesis in the tricuspid position did not become infected and was not removed at reoperation.[1] The bioprosthesis in Patient 14, who died of mitral regurgitation of the bioprosthesis 94 months after its implantation, was recovered at necropsy. The 13 other bioprostheses were recovered at reoperation. The time interval between implantation and operative removal of the bioprostheses ranged from 3 to 94 months (average 39).

In 8 of the 13 patients who underwent reoperation, the procedure was performed because of prosthetic valve stenosis occurring 10 to 60 months (average 34) after implantation. Six of the eight stenosed bioprostheses had been placed in the mitral position, one in the aortic position and one in a pulmonary conduit. Another patient underwent reoperation because of a perivalvular leak 3 months after implantation; the bioprosthesis showed only minimal (clinically insignificant) calcific deposits. Three additional patients underwent reoperation because of prosthetic valve regurgitation caused by cuspal perforation or dehiscence. Patient 8 underwent reoperation because of prosthetic mitral infection causing both stenosis and regurgitation.

Examination after removal disclosed cuspal perforations in six bioprostheses that had been implanted for periods of 18 to 94 months (average 52). One patient had chronic renal insufficiency attributed to cephalothin toxicity; other metabolic diseases were not identified in any of the other patients.

Procedures

After removal, the bioprostheses were fixed with cold, 3 percent glutaraldehyde in 0.1 *M* phosphate buffer, pH 7.2, and processed for light and electron microscopic study. The bioprostheses were radiographed after fixation. For light microscopic examination, selected portions of the cusps were trimmed, decalcified with a mixture of sodium citrate and formic acid and embedded in paraffin. Histologic sections were stained according to the following methods: hematoxy-

lin-eosin, Masson trichrome, Movat pentachrome, phosphotungstic acid-hematoxylin and von Kossa.

For study by transmission electron microscopy, tissues were processed as previously described.[2] For X-ray energy dispersive microanalysis of the calcific deposits, 1,000 Å thick sections of Maraglas®-embedded tissues were prepared, mounted on beryllium grids and examined with an ETEC scanning electron microscope equipped with an EDAX detector.

Results

Gross anatomic observations (Table I): Calcific deposits were grossly evident in 11 of the 14 recovered bioprostheses, and in 9 of these the flexibility and mobility of the cusps were reduced. In 10 of the 11 bioprostheses (from Patients 1 to 7, 10, 12 and 14) the calcific deposits were localized to the cusps; in the remaining bioprosthesis (from Patient 8), they involved infected vegetations.[1] Of the three bioprostheses without grossly evident calcific deposits (from Patients 9, 11 and 13), one (from Patient 9) was covered by thrombotic material, which was the site of infection and calcification evident only on microscopic examination[1,2]; another (from Patient 11) contained noncalcified thrombus, and the remaining one (from Patient 13) had a perforated cusp. The latter two bioprostheses (from Patients 11 and 13) had microscopic calcific deposits in the cuspal connective tissue. Thus, none of the 14 bioprostheses were normal on gross anatomic study.

Six of the 14 bioprostheses had one or more perforations in the cusps; 5 of these had grossly evident calcific deposits, which often were closely adjacent to the perforations. In each of the 10 bioprostheses with calcific deposits in the cusps, these deposits appeared similar and consisted of pale yellow, discrete, usually flat plaques that were raised and projected above both surfaces of the leaflets (Fig. 1 and 2). Less frequently, they formed irregularly shaped, conical or bulbous excrescences 1 to 2 mm in height. The calcific deposits tended to involve all three cusps to a similar extent. When minimal in amount, calcific deposits tended to be localized to areas of the cusps immediately adjacent to the commissures; when more extensive, they formed multiple foci including the areas of apposition of the cusps. The most extensive deposits involved the entire area of each cusp.

Histologic observations: The histologic appearance of the grossly visible calcific deposits (Fig. 3 and 4) was similar in each of the 10 bioprostheses with calcified cusps. The largest calcific deposits always involved the spongiosa (Fig. 3A) and sometimes they extended into immediately adjacent regions of the fibrosa and the ventricularis. Some small calcific deposits were confined entirely either to the fibrosa (Fig. 3B) or to the ventricularis. However, the large calcific deposits in the spongiosa more frequently displaced the other layers of the bioprosthesis, giving the appearance of raised plaques. These deposits often were multinodular, and adjacent nodules were separated from one another by fibrin deposits or by clear spaces (Fig. 4). Some of the latter spaces contained erythrocytes. Elastic fibers were devoid of calcium. The larger calcific deposits actually formed parts of the surfaces of the cusps, whose layered structure appeared to have been completely lost (by erosion of the superficial layers) in such areas. The basophilia of the calcific deposits in histologic sections stained with hematoxylin-eosin was much more pronounced in peripheral than in central regions (Fig. 3).

Calcific deposits also were recognized by electron microscopic study in: (1) the cardiac muscle shelf at the base of the right coronary cusp; (2) adipose tissue cells in the space between the aortic wall and the base of the cusps (Fig. 5A); (3) the aortic media at the level of, and just above, the base of the cusp (Fig. 5B); (4) organizing thrombi on the cuspal surfaces; and (5) infected vege-

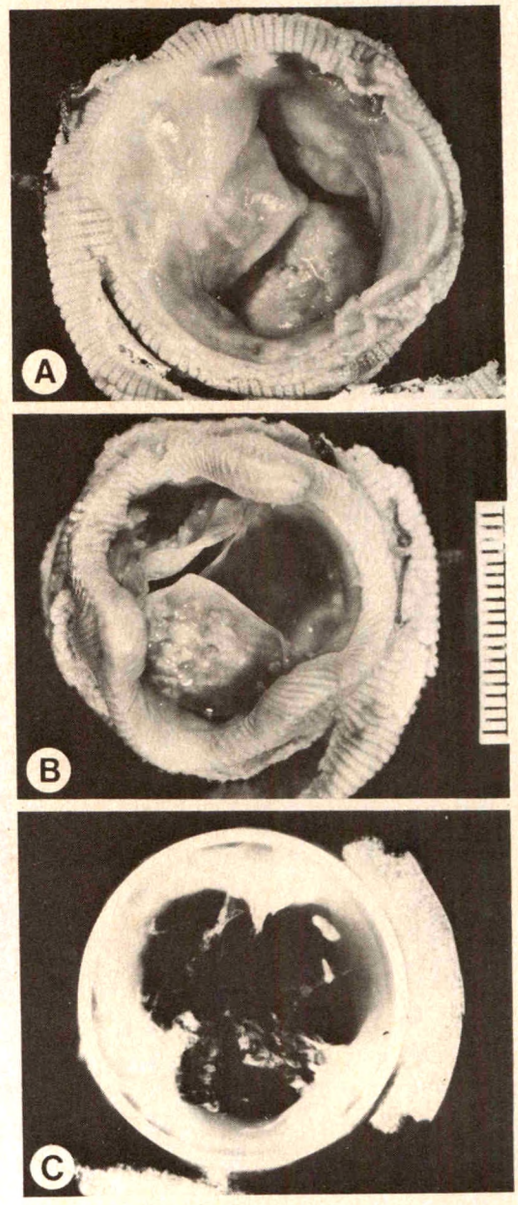

FIGURE 1. Case 12. Photographs of inflow surface (**A**), outflow surface (**B**) and roentgenogram (**C**) of bioprosthesis operatively removed, because of severe stenosis, 48 months after implantation in the mitral position. Calcific deposits are present in each cusp and are prominent in the commissural regions.

tations produced by staphylococci (Patient 8). In the first two of these sites, the calcific deposits were small. However, in the aortic wall the deposits were larger and formed plaques that extended throughout the media. Such deposits, which involved both the smooth muscle cells and the extracellular spaces, had strongly basophilic edges and much less basophilic cores (Fig. 5B). The deposits in the aortic wall were not continuous with those in the cusps, and therefore did not produce bioprosthetic dysfunction. The deposits in young and old patients were similar histologically.

Other histologic changes observed in the biopros theses were (1) separation (delamination) of adjacen layers of connective tissue in the cusps, particularly i the spongiosa, leaving clear spaces that often were fille by proteinaceous material[2]; (2) loss of proteoglyca material from the spongiosa (best demonstrated wit the Movat stain); (3) deposition of mononuclear cell mostly macrophages, and multinucleated giant cells o the surfaces of the cusps, particularly in the outflo surfaces; and (4) focal thinning of the cusps, with frayin and erosion of the connective tissue. In Patients 3 to 5

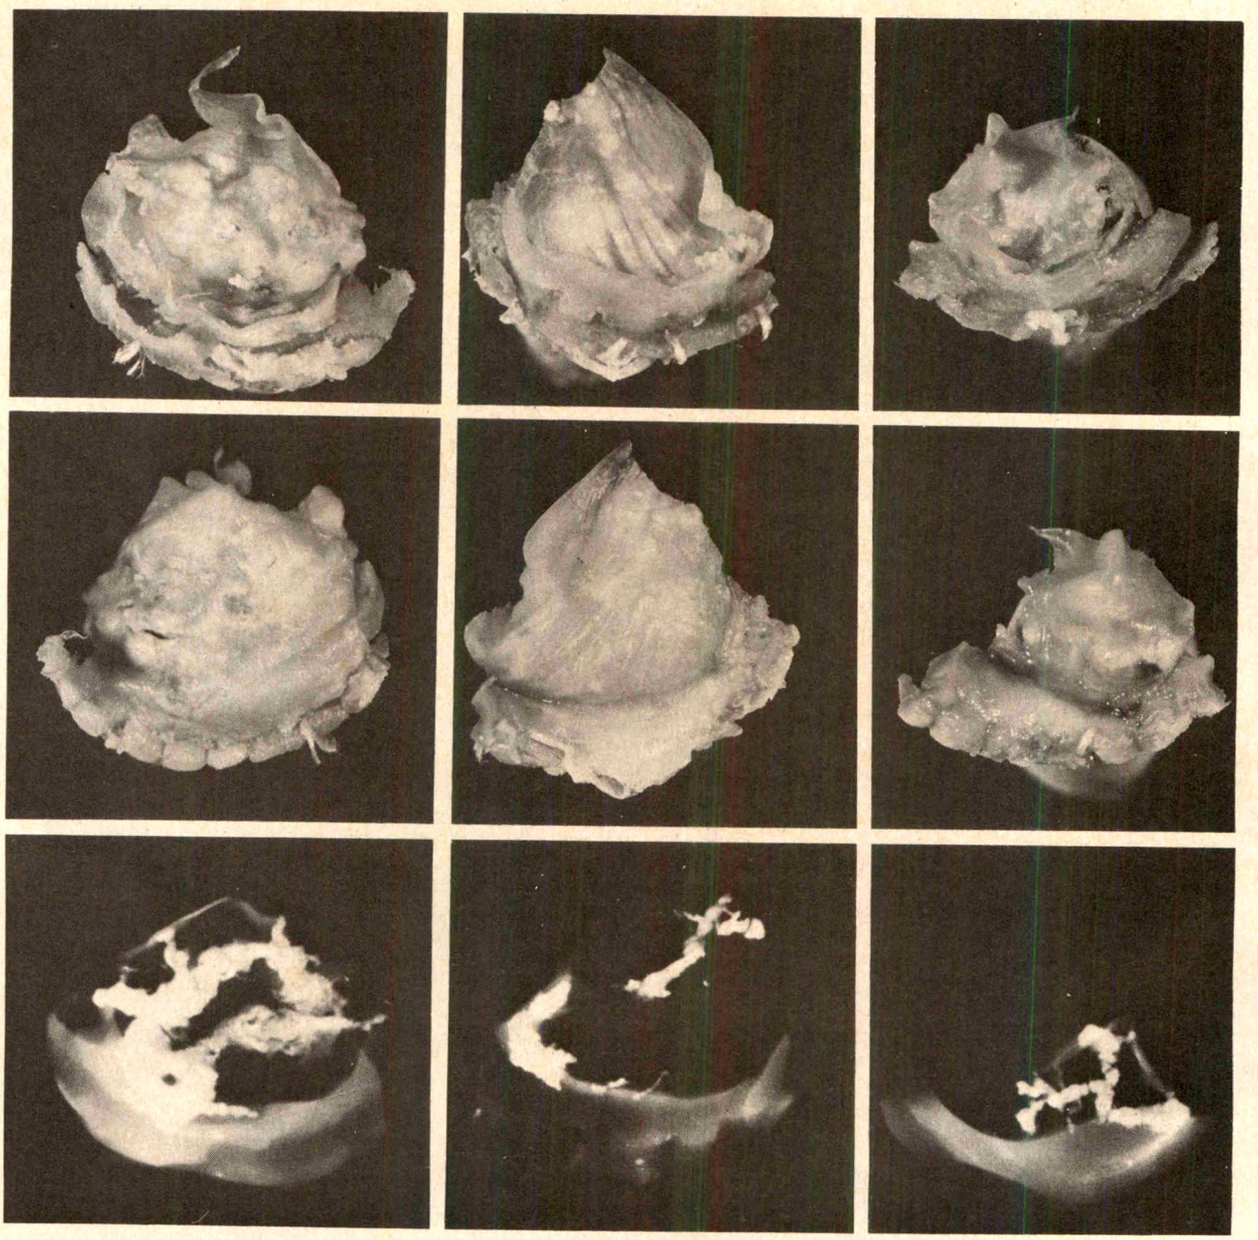

FIGURE 2. Case 1. Outflow surfaces (**top**), inflow surfaces (**middle**) and roentgenograms (**bottom**) of the cusps of bioprosthesis removed at reoperation because of severe stenosis, 41 months after implantation in the mitral position. The true extent of the calcific deposits is difficult to assess from visual inspection, and the roentgenograms show that they consist of streaks that bear no relation to the normal anatomic features of the cusps.

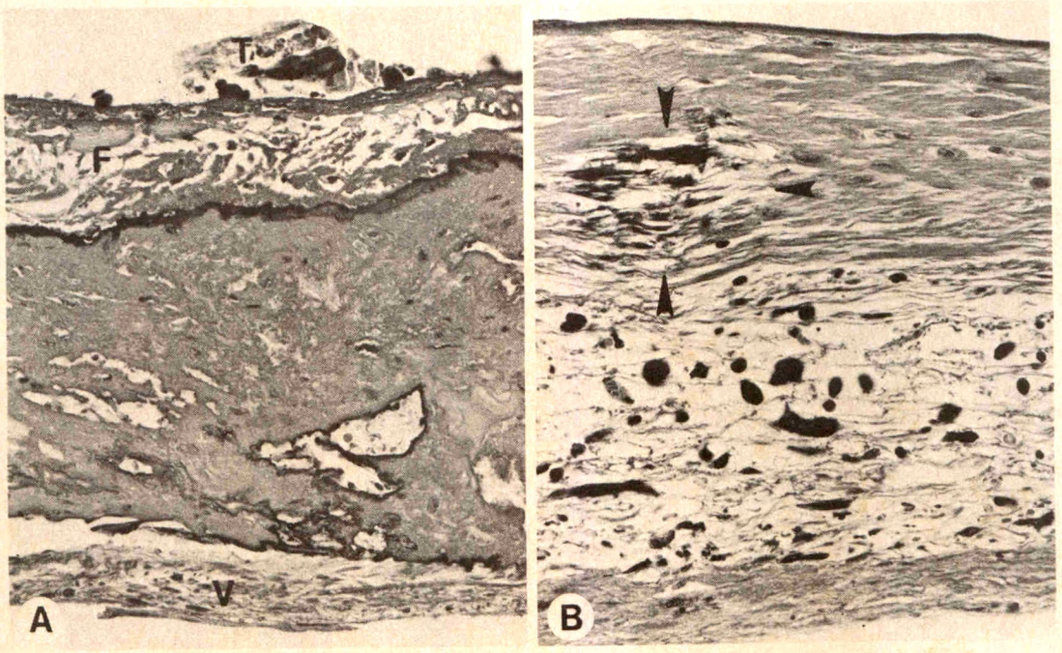

FIGURE 3. Case 3. Light micrographs of calcific deposits in the stenotic bioprosthesis operatively removed 30 months after implantation in the mitral position. **A,** deposit that fills area corresponding to spongiosa of normal cusp. The fibrosa (F) shown at **top** is partially disrupted; a small thrombus (T) is present on the outflow surface, and the ventricularis (V) is shown at **bottom.** Note the dark irregular borders of the calcific deposit and the empty spaces that it still contains (compare with the appearance of the spongiosa in **B. B,** small calcific deposit (**arrowheads**) is localized in fibrosa of bioprosthesis. Note the empty appearance of the spongiosa, which is delaminated and has lost its proteoglycan material. The dark material in the spongiosa probably represents precipitated plasma protein components. The ventricularis appears normal. (Hematoxylin-eosin ×250 [**A**] and Novat pentachrome ×250 [**B**], both reduced by 20 percent.)

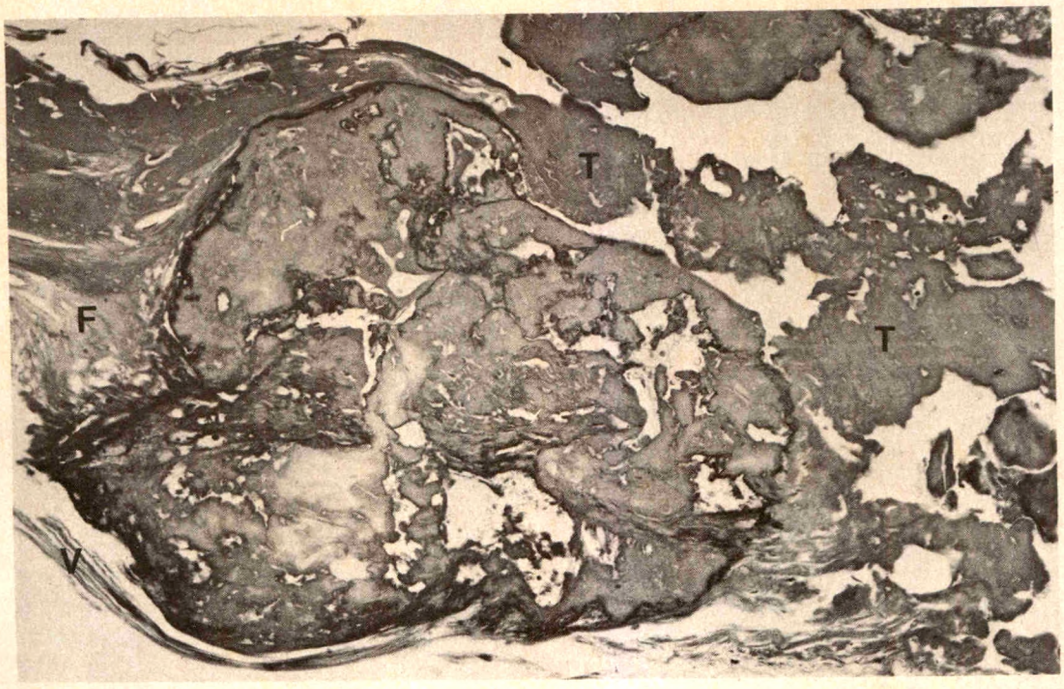

FIGURE 4. Case 3. Histologic appearance of large multinodular calcific deposit occupying practically the entire thickness of the cusp and associated with a large amount of thrombotic material (T), mostly fibrin. The structure of the cusp has been severely altered. Both the fibrosa (F) and the ventricularis (V) appear eroded on the **left** and completely disrupted on the **right.** (Movat pentachrome ×250, reduced by 20 percent.)

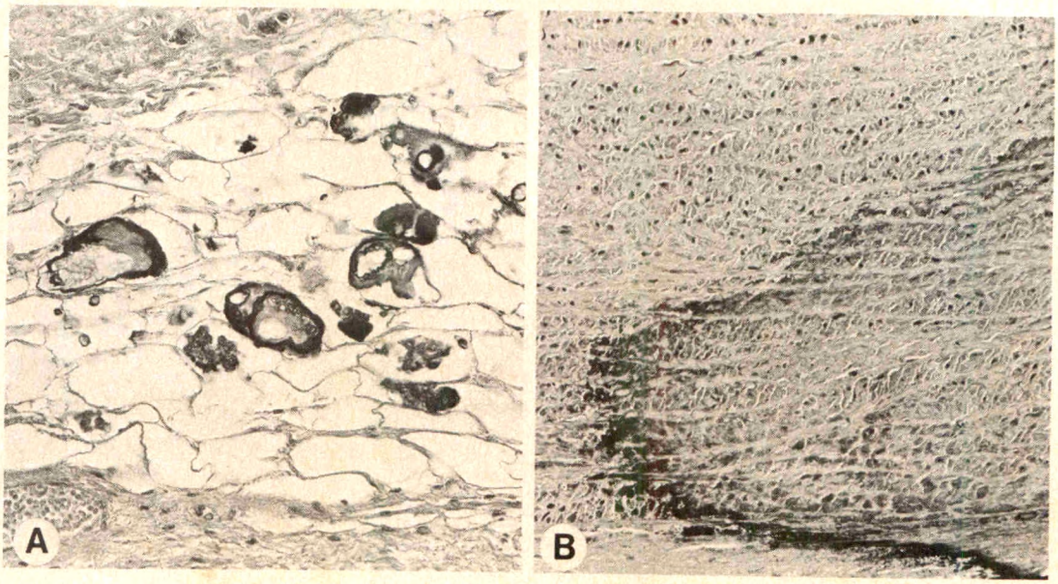

FIGURE 5. Case 8. Calcific deposits in adipose tissue cells at base of cusp (**A**) and in aortic wall (**B**). (Hematoxylin-eosin ×250 and ×150, respectively, reduced by 20 percent.)

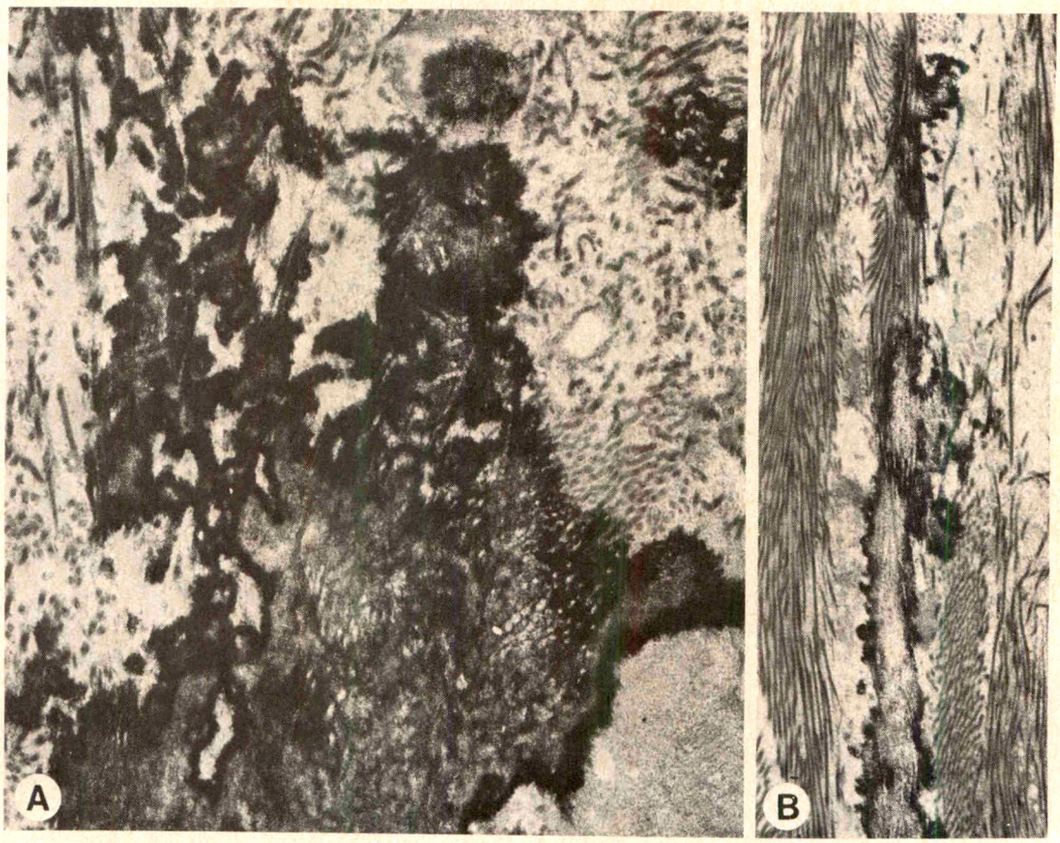

FIGURE 6. Case 3. Electron micrographs of calcific deposits associated with collagen fibrils. **A**, electron-dense crystals of calcium phosphate have completely surrounded several bundles of collagen fibrils at the periphery of a large calcific mass. **B**, small calcific deposit appears to be developing associated with a bundle of collagen fibrils. Note the characteristically dense border of the deposit (×22,000 [**A**] and ×15,000 [**B**], reduced by 20 percent.)

10, 13 and 14, the latter changes were associated with perforation of one or more of the cusps.

Ultrastructural observations: Certain early and late ultrastructural changes in porcine bioprostheses have been described in detail in previous publications from this laboratory.[2,3] Therefore, only changes related to calcification are described herein. Two types of calcific deposits were considered to be of significance in producing bioprosthetic stenosis: deposits related to calcification of cuspal connective tissue structures and deposits related to calcification of surface thrombi.

Calcification of cuspal connective tissue structures consistently involved collagen fibrils (Fig. 6 and 7) but seldom involved cell components of the cusps, and did not involve elastic fibers. Most deposits involved areas in which the collagen fibrils were relatively loosely arranged rather than tightly packed. Calcific deposits associated with collagen fibrils showed three different patterns of organization. In the first of these (Fig. 7, A and B), the calcific deposits directly involved the collagen fibrils but did not extend into the interfibrillary spaces. In the second (Fig. 6, A and B and 7, C and D), the calcific deposits were localized in the periphery of the collagen fibrils and in the interfibrillary spaces; however, the interior of the collagen fibrils was not involved, and the fibrils therefore appeared as electron-lucent cylinders surrounded by an extremely dense calcified matrix. In the third pattern (Fig. 7C), the cal-

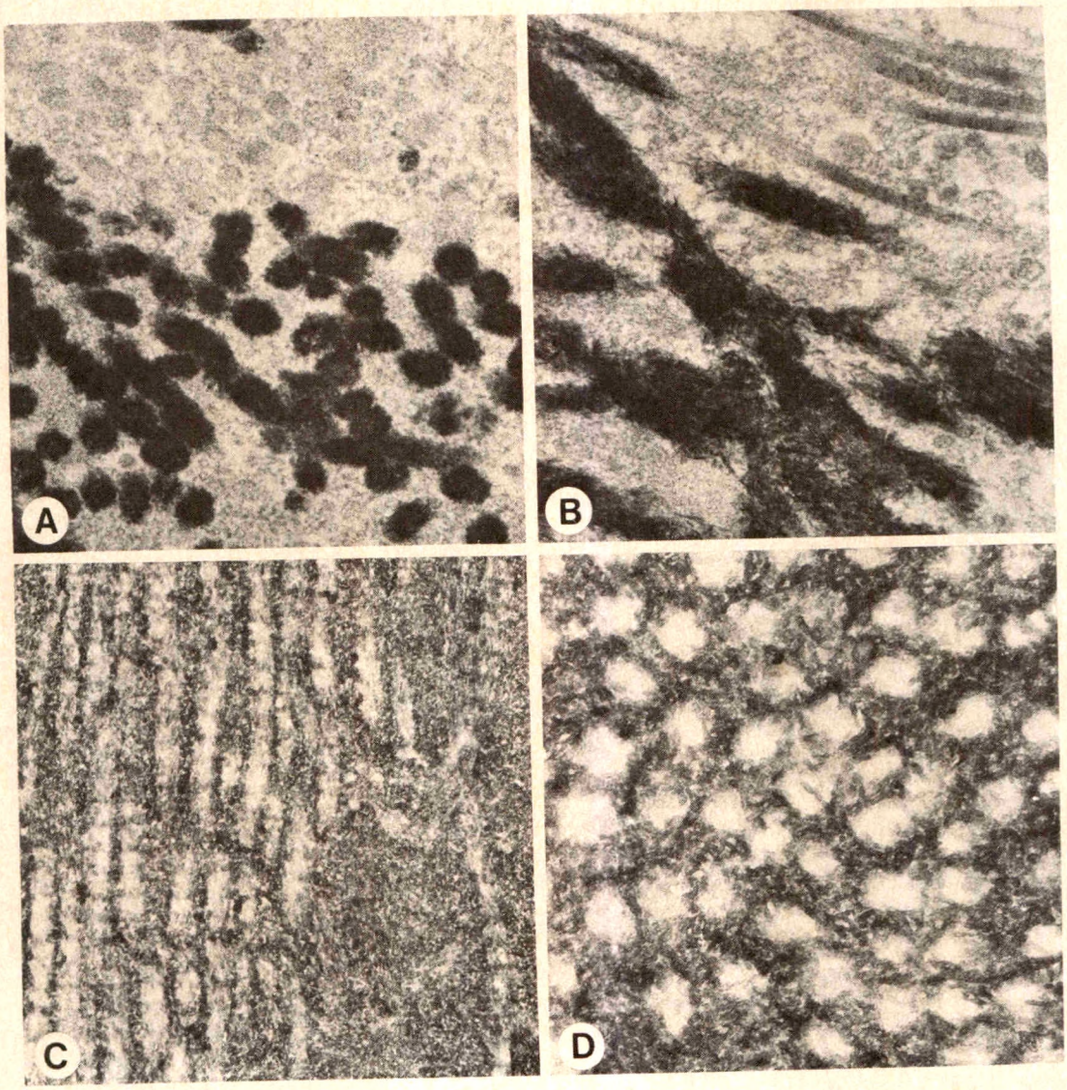

FIGURE 7. High magnification views of calcific deposits associated with collagen fibrils. Case 1, **A** and **C**; Case 3, **B**; Case 6, **D**. **A** and **B**, transverse (**A**) and longitudinal (**B**) views of deposits that involve the entire thickness of the collagen fibrils. In both views the calcified fibrils appear larger than adjacent uninvolved fibrils, suggesting spread of crystal growth into the interfibrillary spaces (×75,000 and ×60,000, respectively, reduced by 20 percent.) **C** and **D**, calcific deposits in both of these areas occupy interfibrillary spaces. In **C** the crystals are also present in the interior of the collagen fibrils, some of which (**upper right**) are barely discernible. In **D**, the crystalline nature of the calcific deposits is evident (×60,000 and ×127,000, respectively, reduced by 20 percent).

cific deposits occupied both the interfibrillary spaces and the interior of the fibrils, thus giving the deposits a relatively homogeneous appearance. This homogeneous pattern was characteristically present throughout the central areas of large calcific deposits. In contrast, the interfibrillary pattern was found either at the periphery of large masses or throughout small masses. Involvement of the collagen fibrils with sparing of the interfibrillary spaces was found only in small scattered groups of collagen fibrils, and not in association with large calcific deposits.

Most of the calcific deposits associated with connective tissue showed a crystalline substructure when examined at high magnifications, regardless of their pattern of organization with respect to the collagen fibrils. The crystals were cylindrical in shape and measured from 280 to 330 Å in length and from 65 to 80 Å in width. These crystals often were mixed with material that appeared amorphous even at very high magnification. Energy dispersive X-ray microanalysis revealed the presence of calcium and phosphorus in these crystals, and X-ray diffraction analysis disclosed patterns similar to that of apatite. Degeneration of the collagen (usually of severe degree) was often associated with the calcific deposits, but the most severely degenerated collagen was not necessarily the most calcified, and extensive calcific deposits sometimes were evident in areas where collagen showed little or no change.

Small calcific deposits were occasionally found to overlie mitochondria (Fig. 8A) and rarely, nuclei (Fig. 8B) of porcine cells in the cusps. They were located i areas in which other structures were severely calcifie and they constituted a small fraction of the total c calcific deposits. No structures resembling the "matri vesicles" of other calcifying tissues[23,24] were found i any bioprosthetic cusp.

Calcific deposits associated with vegetations an thrombi were composed of plate- or needle-shape crystals (Fig. 9), which measured up to 80 Å in maxima thickness and up to 1,000 Å in largest diameter. Th smallest of these deposits were located within remnant or "ghosts" of platelets and leukocytes that appeare to have been trapped within a mesh of fibrin strands These deposits usually were within mitochondria. Th fibrin strands were not sites of deposition of calcifi crystals.

Discussion

Features of Calcific Deposits in Porcine Bioprostheses:

Predisposing factors: This study reveals that cal cification of porcine bioprostheses can occur in adult as well as in children, that the most important sites o formation of calcific deposits in both age groups are th connective tissue in the cusps and thrombi and vege tations on the surfaces, and that calcific deposits are a important cause of prosthetic valve dysfunction. Ou findings are in accord with those of previous clinica studies[4–22] of calcification of porcine bioprostheses

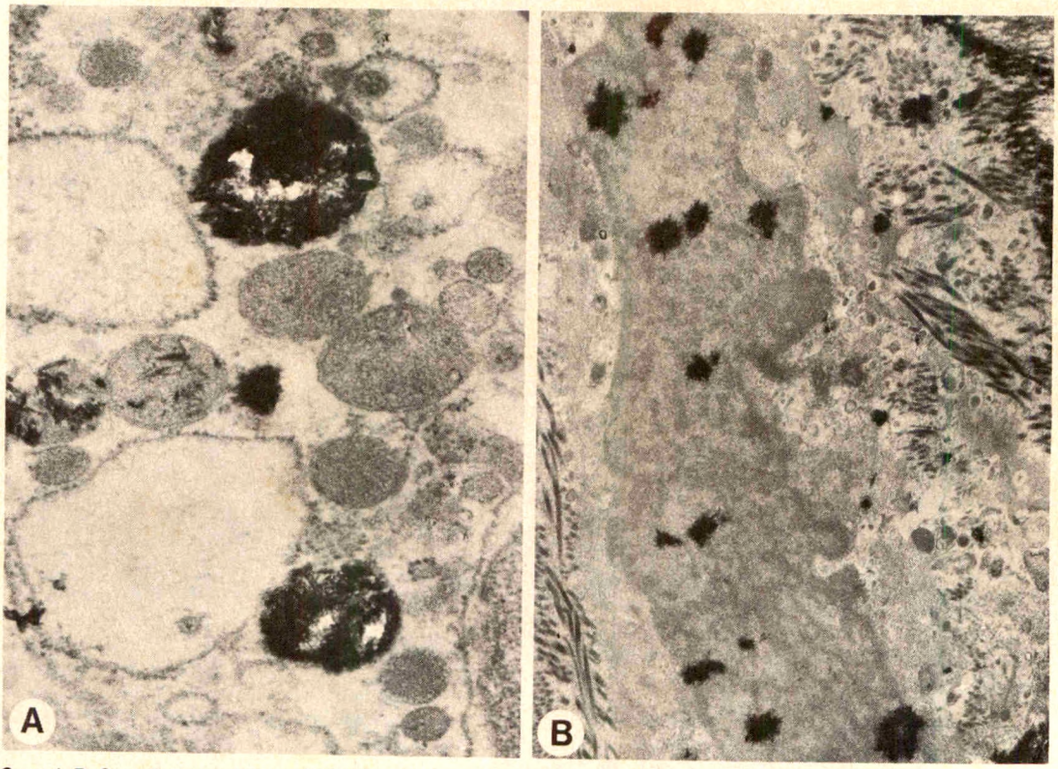

FIGURE 8. A, Case 1; **B,** Case 3. Intracellular calcific deposits in valvular connective tissue cells of porcine origin are few and small, and involved mitochondria (**A**) and nuclei (**B**), (×44,000 [**A**] and ×18,000 [**B**], reduced by 20 percent).

Those studies (Table II) have documented the occurrence of calcification in a total of 37 bioprostheses implanted in 34 patients. The time between implantation and removal of the bioprostheses averaged 28 months, which was less than the mean time of 39 months in our patients. This difference reflects the greater number of children in Table II than in our group of patients. The average age of our patients was 32 years; that of the patients in Table II was 23 years. Although these data indicate that calcification of porcine bioprostheses is more frequent and develops more rapidly in children and young adults than in older patients, our study shows that the gross anatomic, histologic and ultrastructural features of the calcific deposits are the same in both age groups, thus suggesting that the causative processes are similar. Evidence of infection was present in the calcified valves in two of our patients and in seven of the patients previously described (Table II). Metabolic factors that could have contributed to the formation of calcific deposits were identified in only one of our patients and in only three of the patients in Table II; in all four patients, the factor was chronic renal insufficiency.

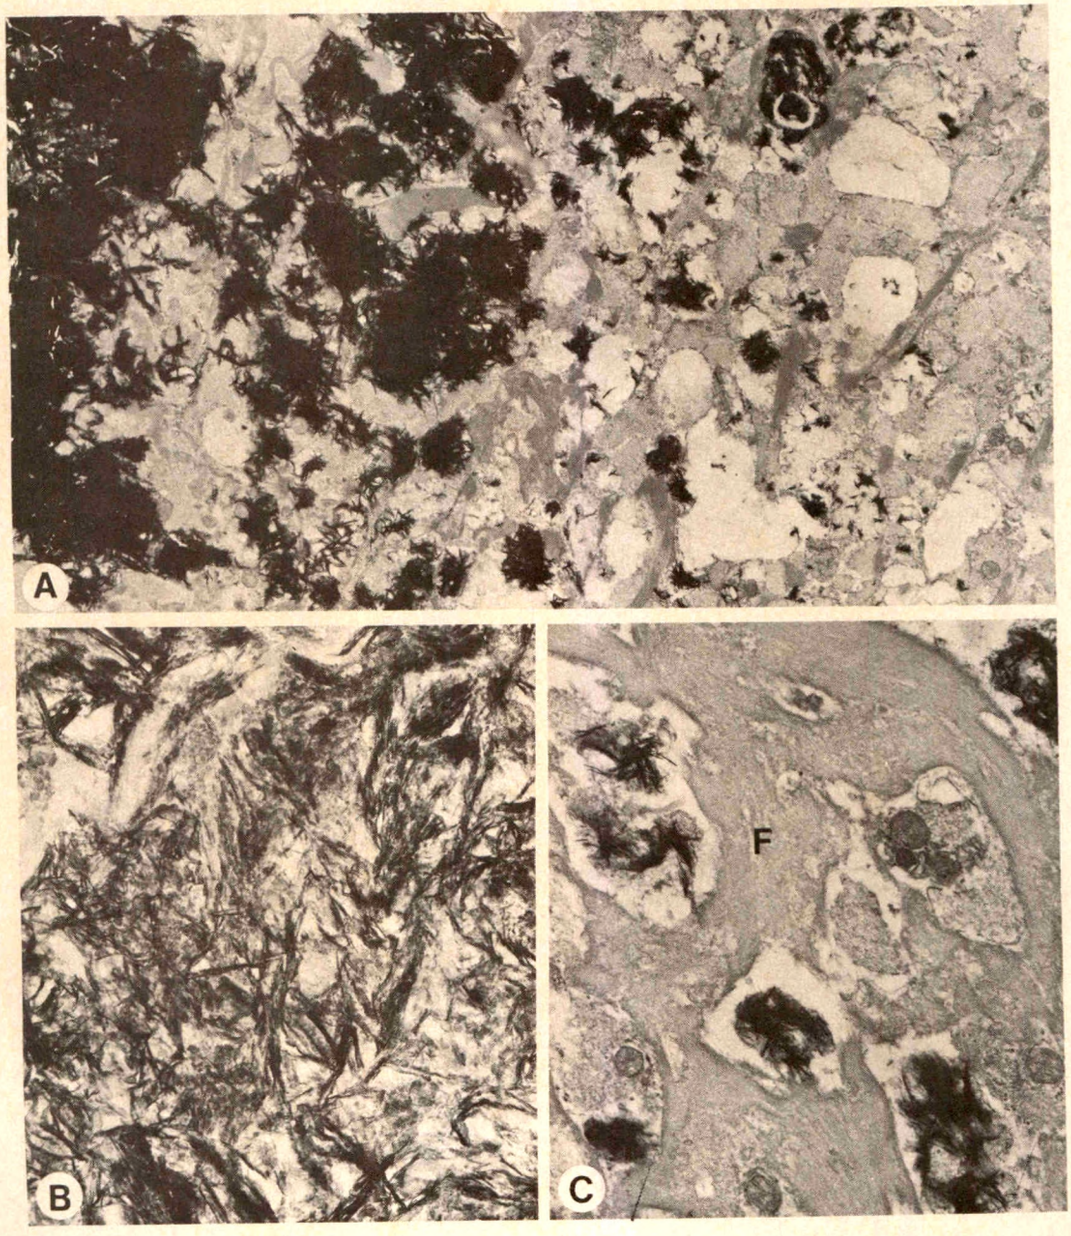

FIGURE 9. Case 8. Calcific deposits associated with thrombotic material on the surface of the bioprosthesis. **A**, low magnification view showin large masses of electron-dense crystals adjacent to thrombus. **B**, high magnification view demonstrating the plate-like structure of the crystal shown in **A**. **C**, remnants of platelets trapped in fibrin mesh (F) contain calcific deposits. (×13,000 [**A**], ×25,700 [**B**], ×37,000 [**C**], reduced b 20 percent.)

Thus, coexisting metabolic disorders are not recognizable in the majority of patients in whom calcific deposits develop in porcine bioprostheses.

Frequency: Such deposits are common. The 14 calcified bioprostheses reported in our study represent nearly 50 percent of all bioprostheses examined with electron microscopy in our laboratory. Because these bioprostheses were submitted for study for a variety of reasons, they do not constitute a representative sample of all implanted porcine bioprostheses. Nevertheless, in the only large institutional experience thus far reported, Billingham et al.[25] observed calcific deposits in 17 (34 percent) of 50 porcine bioprostheses recovered at Stanford University Hospital between 1974 and 1978. Failure to detect calcific deposits may be related to the fact that histologic sections of these bioprostheses usually are taken from the central portions of the cusps. Because the earliest deposits are most frequently located near the commissures, such deposits may be missed. In our experience, the most sensitive technique for detecting calcific deposits in porcine bioprostheses is X-ray examination of the entire explanted bioprosthesis.

Valve dysfunction: Factors such as size and location will determine whether the calcific deposits cause bioprosthetic dysfunction. Recent observations indicate that significant degrees of bioprosthetic stenosis related to calcification of porcine bioprostheses can occur in relatively asymptomatic patients.[26] This clinical situation parallels that which is well known to occur in stenosis affecting natural mitral values. Therefore, the lack of symptoms does not exclude the possibility of significant bioprosthetic stenosis.

Mechanisms of Calcific Deposits

Calcific deposits have been found in porcine bioprostheses implanted in experimental animals[27,28] as well as in other types of bioprostheses implanted in patients, including dura mater valves,[29] fascia lata valves,[28,30–33] porcine valves treated with formalin,[5] periodate[34] or mercuric salts,[5] fresh[28,35] or glutaraldehyde-treated[36] pericardial bioprostheses, and homografts preserved by antibiotics, beta-propriolactone, freeze-drying or irradiation.[37–42] In addition, calcific deposits involving thrombotic material deposited on the sewing ring[43] or on Teflon® cusps[35] also have occurred

in rigid-framed valves. The actual frequency of these changes has not been studied and the histologic features of calcific deposits in prosthetic heart valves have been the subject of few studies. The aortic wall in homografts has been reported to undergo much more severe calcification than the cusps.[40,44,45] The localization of calcific deposits in valve bioprostheses has not been studied in detail, although calcified collagen has been observed in variously prepared porcine bioprostheses.[5] In this study, several sites of calcification were identified in porcine bioprostheses. Among these were collagen, organized thrombi and vegetations, mitochondria and nuclei of cells of porcine origin, and the cytoplasm of adipose tissue cells. Of these sites, collagen and thrombotic material appeared to be the most important; the deposits at these sites represent the results of different mechanisms and therefore will be considered separately.

Calcification of collagen: The process of normal calcification of tissues such as bone, cartilage and teeth basically consists of the deposition of a crystalline inorganic phase, composed of a form of calcium phosphate known as hydroxyapatite, on a preexisting matrix of collagen fibrils that are associated with proteoglycans (complexes of proteins and acid mucopolysaccharides), noncollagen glycoproteins, peptides, lipids and other components of connective tissue ground substance.[46,47] The calcium and phosphate ions are derived from the circulating blood and can come into contact with the calcifying matrix either directly, by simple diffusion or after being absorbed and concentrated within connective tissue cells.[46]

The nature of the initial sites of formation of calcific deposits in the organic matrix of calcifying connective tissues is still the subject of controversy, although there is complete agreement that the end result, calcification of collagen, is similar regardless of the initial events. In early stages of development of bone, cartilage and dentine, the process of calcium deposition is initiated by structures known as matrix vesicles.[23,24] These vesicles are secreted by connective tissue cells, are limited by single trilaminar membranes and contain small needle-shaped crystals of calcium phosphate. These crystals grow in size as the membranes of the matrix vesicles rupture, and extension and coalescence of crystal growth lead to calcification of the collagen. In many instances other than early development, the process of calcification of collagenous structures occurs without participation of matrix vesicles, and in these instances the collagen itself becomes the site of formation and growth of nuclei of crystallization.[46,47] This mechanism appears to be responsible for calcification of connective tissue in porcine bioprostheses, in which we found no matrix vesicles. Porcine valve connective tissue cells cannot participate in a process of secretion of matrix vesicles, because these cells are killed by the commercial processing of glutaraldehyde. Direct involvement of collagen in the formation of calcific deposits also is suggested by our finding of small foci of calcium phosphate crystals overlying collagen fibrils. The morphologic features of calcified collagen in porcine bioprostheses are similar to those of calcific deposits occurring spontaneously and induced experimentally, both in vivo and in vitro, in collagen in tendons of animals[48–53] and in skeletal muscle of human beings with fibrositis (myositis) ossificans.[48]

The initial deposits of calcium in mineralizing connective tissues consist of amorphous calcium phosphate; this amorphous material is gradually transformed into crystalline hydroxyapatite.[52,53] The current concepts of the relation of the collagen to the calcific deposits are that (1) phosphate groups form covalent bonds that connect the organic and inorganic components in calcified tissues; (2) epsilon-amino groups present in lysine and hydroxylysine are of importance in forming the bonds between native collagen and phosphate groups; (3) many of the hydroxylysine residues normally are either linked (glycosylated) to noncollagen carbohydrate material or modified to form covalent cross-links; and (4) the three dimensional structure of the collagen fibril is also of importance in determining the availability of these groups for reacting with phosphate and serving as centers of nucleation.[46,53] Thus, all collagen appears to be theoretically capable of calcifying. The reason that many areas of collagen do not calcify in vivo has been attributed to the presence in the ground substance in such areas of proteoglycans and glycoproteins, which are associated with collagen[53,54] and which mask or block the sites that would react with phosphate and calcium to become nucleation centers.[53] This concept appears to be applicable to the calcification of collagen in porcine valve bioprostheses. This calcification is most marked in the spongiosa, the layer that in the native porcine valve is most abundant in proteoglycan material. We[2] have previously shown that this material is lost after commercial processing and implantation, and we believe that this loss of proteoglycan may predispose to calcification for two reasons. The first reason is the uncovering of phosphate-binding sites in the collagen, as previously mentioned. The second reason is the loss of proteoglycan, leaving empty spaces in the spongiosa; these spaces may become filled with deposits of plasma proteins and other blood constituents, which in turn may provide additional sites of calcification.

The possible participation of other proteins in calcification of collagen is suggested by the recent identification of several different classes of proteins that have a high binding affinity for calcium.[55–59] This binding affinity is related to their content of gamma-carboxyglutamic acid, an unusual amino acid that is formed by a reaction that requires vitamin K and bicarbonate. Some of these proteins (the vitamin K-dependent blood clotting proteins) are present in normal blood; others have been found in tissues undergoing normal (bone) or abnormal (renal calculi, atherosclerotic plaques, skin in scleroderma and dermatomyositis) calcification.[55–57] Levy et al.[58,59] found gamma-carboxyglutamic acid in hydrolysates of protein material extracted from porcine bioprostheses that had manifested calcific deposits after being implanted in patients and from calcified native aortic valves, but not from noncalcified bioprostheses. The origin (from circulating blood or from in situ synthesis), the localization in the

bioprosthetic tissue and the significance of this protein material in porcine valves have not yet been established. Nevertheless, these findings are important because they represent a new, incompletely understood aspect of biologic calcification.

The role of pretreatment with glutaraldehyde in modifying the tendency of porcine bioprostheses to undergo calcification is unclear. Such pretreatment introduces several additional cross-links in collagen, thus stabilizing the structure of the fibrils. This finding suggests that the inability of calcium and phosphate to penetrate into the highly cross-linked interior of the collagen fibrils may explain why calcific deposits often (Fig. 7, C and D) do not extend into the cores of collagen fibrils in porcine bioprostheses. Such penetration would result in complete calcification of the collagen fibrils (Fig. 7, A and B), which was a less frequent microscopic finding in our study. Glutaraldehyde reacts in a complex manner with free amino groups in lysine and hydroxylysine,[60] thus possibly preventing them from reacting with phosphate to initiate the formation of calcific deposits. However, it is probable that new lysine and hydroxylysine residues (or other reactive residues) are brought into the tissue after implantation through plasma proteins that penetrate between collagen fibers and permeate the connective tissue framework. A large incidence of calcification developed in porcine bioprostheses that had been prepared for clinical use by treatment first with sodium metaperiodate, a mild oxidizing agent,[61] and ethylene glycol and then with glutaraldehyde.[34] The exact relation between this oxidative process and the subsequent development of calcification has not been clarified. It is known from other observations[46,62] that the process of calcification of biologic materials is subject to considerable modifications by a wide variety of agents, including hormones (parathormone and calcitonin), vitamin D and alkaline phosphatase (an enzyme that hydrolyzes various phosphate esters and thus generates inorganic phosphate, which contributes to calcification). Thus, calcification of collagen in porcine bioprostheses tends to be most marked in children, in whom the balance of hormonal and metabolic factors clearly favors the deposition of calcium phosphate in collagen in other tissues such as bone. A predisposition to calcification of soft tissues is well known to occur in patients with chronic renal disease and secondary hyperparathyroidism.[63]

Calcification of thrombotic material: Thrombi in various sites are known to calcify, most notably in the left atrium of adults with mitral stenosis. The mechanisms of formation of calcific deposits in thrombi have not been studied ultrastructurally. Our observations show that the sites of initial calcification in thrombi and vegetations are platelets and leukocytes that become trapped in the fibrin mesh. The intracellular components that undergo calcification are the mitochondria, and crystal growth from these sites leads to the formation of large confluent and calcific masses. These masses in turn probably induce the formation of additional thrombi, and repeated episodes of thrombosis and calcification probably account for the layered or laminated appearance of calcific deposits of this type. As in the case of calcification of collagen, calcification of mitochondria represents a commonly occurring biologic phenomenon. Mitochondria are the sites of calcification in ischemic heart muscle cells[64,65] and in other cell types in many other conditions.[66] Thus, mitochondrial calcification constitutes a basic mechanism for the initiation of intracellular calcification, and from mitochondria the deposits can spread and fill the entire cell. This mechanism is important with respect to host cells in surface thrombi, but seems to be operational only to an extremely limited extent in the porcine cells in bioprostheses. Perhaps this is so because the accumulation of calcium in mitochondria, at least in its initial stages, is an active process that occurs in cells that may be injured but are still alive.[66] This process excludes porcine cells, which are killed by the glutaraldehyde processing.

Implications: Calcific deposits are commonly found in implanted porcine bioprostheses. In some of these prostheses, particularly in those implanted in children and young adults, they are the cause of important degrees of bioprosthetic dysfunction. They can be caused by calcification of cuspal collagen or of thrombotic material on the cuspal surfaces. An understanding of the mechanisms of formation of these two types of deposits is essential for the formulation of measures designed to prevent calcification of tissue valves.

Addendum

Four very recent reports[67–70] have provided additional documentation of the occurrence of early, severe calcification of porcine valve bioprostheses implanted in children and young adults without metabolic diseases or infective endocarditis. In some patients[68,69] the calcification was associated with degeneration of collagen. It was suggested[69] that this calcification may be promoted by host factors related to calcium homeostasis.

RICHARD C. DAVIS, Jr., MD, PhD, LTC, MC
TROY H. WILLIAMS, MD, COL, MC

Aurora, Colorado

Twenty patients with a prosthetic valve (Ionescu-Shiley or Bjork-Shiley) in the aortic position were studied for evidence of intravascular hemolysis. Serum lactic dehydrogenase and serum haptoglobin levels were used as the most sensitive indicators of hemolysis. Elevated concentrations of lactic dehydrogenase were found in all 10 patients with an Ionescu-Shiley prosthesis (mean 402 IU/liter) and in 7 of 10 patients with a Bjork-Shiley prosthesis (mean 234 IU/liter). The mean serum haptoglobin was 15 mg/dl (range 10 to 28) in patients with the Ionescu-Shiley valve and 96 mg/dl (15 to 284) for those with the Bjork-Shiley valve. This study indicates the presence of chronic intravascular hemolysis in patients with the Ionescu-Shiley aortic valve. The increase in lactic dehydrogenase was significantly greater in patients with the Ionescu-Shiley prosthesis than in those with the Bjork-Shiley prosthesis, indicating a slightly shorter red cell life span in the former group.

Intravascular hemolysis in patients with prosthetic heart valves has been recorded for ball valve and disc prostheses.[1–4] The newer tissue valves have been the subject of fewer studies.[5–7] Recent reports[8–10] have stated that the Ionescu-Shiley pericardial xenograft does not cause detectable hemolysis. In contrast, we[11] have found evidence of hemolysis associated with this prosthesis in the mitral position. In this study we attempted to assess the incidence and severity of hemolysis in 10 patients with the Ionescu-Shiley xenograft in the aortic position. The results were compared with those found in 10 patients with a Bjork-Shiley aortic valve disc prosthesis.

Methods

Patients: Twenty patients (14 men and 6 women) who had undergone aortic valve replacement were studied; of these, 10 patients had valve replacement with the Ionescu-Shiley xenograft and 10 with the Bjork-Shiley prosthetic valve. In the group with the Ionescu-Shiley valve, the hematologic studies were performed at a mean interval of 10.6 months (range 3 to 16) after aortic valve replacement; five valve sizes (anulus diameter 19, 21, 23, 25 and 27 mm) were used. The mean age of the patients in this group was 53.8 years (range 20 to 72). The group with the Bjork-Shiley valve was studied at a mean interval of 31 months (range 3 to 48) after operation; three valve sizes (anulus diameter 21, 23 and 25 mm) were studied. The mean age of the patients in this group was 58.5 years (range 47 to 65).

Of the 10 patients with an Ionescu-Shiley valve, 9 underwent postoperative hemodynamic and angiographic investigations; 8 of the 9 had a competent valve, and all had a small transvalve gradient. One patient had a grade I/IV paravalve leak.

Laboratory studies: To assess hemolysis, the following laboratory tests were performed: a complete blood count with reticulocyte count, platelet count, red cell indexes and examination of the blood smear. Other studies included determination, by standard methods, of serum haptoglobin, serum lactate dehydro-

TABLE I

Comparison of Hematologic Variables in 10 Patients With the Ionescu-Shiley and 10 With the Bjork-Shiley Aortic Prosthesis

	Serum LDH (IU/liter)	SGOT (IU/liter)	Serum Haptoglobin (mg/dl)	Hemoglobin (g/100 ml)	Hematocrit (%)	Reticulocyte Count (%)
Normal range	90–215	10–50	170–300	12.5–18	38 to 52	<2
Ionescu-Shiley						
Mean	402	37	15	13.8	40	2.3
Range	294–580	28–48	10–28	12.5–16	8–46	0.5–5.6
Bjork-Shiley						
Mean	234	31	96	14.5	42	0.8
Range	178–287	24–37	15–284	13.1–16	38–47	0.5–1.0
p value	<0.05	NS	<0.05	NS	NS	<0.05

LDH = lactic dehydrogenase; n = number; NS = not significant; p = probability (p <0.05 = significant); SGOT = serum glutamic oxaloacetic transaminase.

genase with isoenzymes, serum glutamic oxaloacetic transaminase (SGOT) and total bilirubin concentration. Serum iron, total iron-binding capacity, iron saturation, urine hemosiderin were also measured and Coombs' test was performed.

Clinical features: Clinical assessment of all patients, together with hemodynamic and angiographic evaluation (9 of the 10 patients with an Ionescu-Shiley valve), revealed no apparent contributory cause of the hemolysis, with the exception of a mild grade (I/IV) paravalve leak in one patient with the Ionescu-Shiley valve; in addition, one patient with the latter valve had a sinus of Valsalva aneurysm repaired with a Dacron® patch. There were no recent episodes of myocardial infarction by clinical or electrocardiographic evidence. The patients showed no evidence of autoimmune disease (negative Coombs' test). Hence, any intravascular hemolysis was wholly attributable to the prosthesis in most patients.

Student's t *test was used for statistical evaluation of the results.* Probability (p) values greater than 0.05 were considered not statistically significant.

Results

Serum lactic dehydrogenase: Laboratory data obtained from patients with the two types of aortic valve prosthesis are summarized in Table I and Figure 1. The mean value for serum lactic dehydrogenase in patients with an Ionescu-Shiley valve (402 IU/liter) was significantly ($p < 0.05$) greater than the mean value for patients with a Bjork-Shiley valve (234 IU/liter). In the latter group, lactic dehydrogenase values were only slightly higher than the normal range. The highest value (580 IU/liter) was obtained in a patient with an Ionescu-Shiley valve who had the mild paravalve leak.

Serum haptoglobin: Reduced serum haptoglobin was found in 100 percent of patients with an Ionescu-Shiley prosthesis (less than 50 mg/dl in all cases), but in only 80 percent of patients with a Bjork-Shiley valve (two patients had normal values). Mean values for haptoglobin were lower than normal in both patient

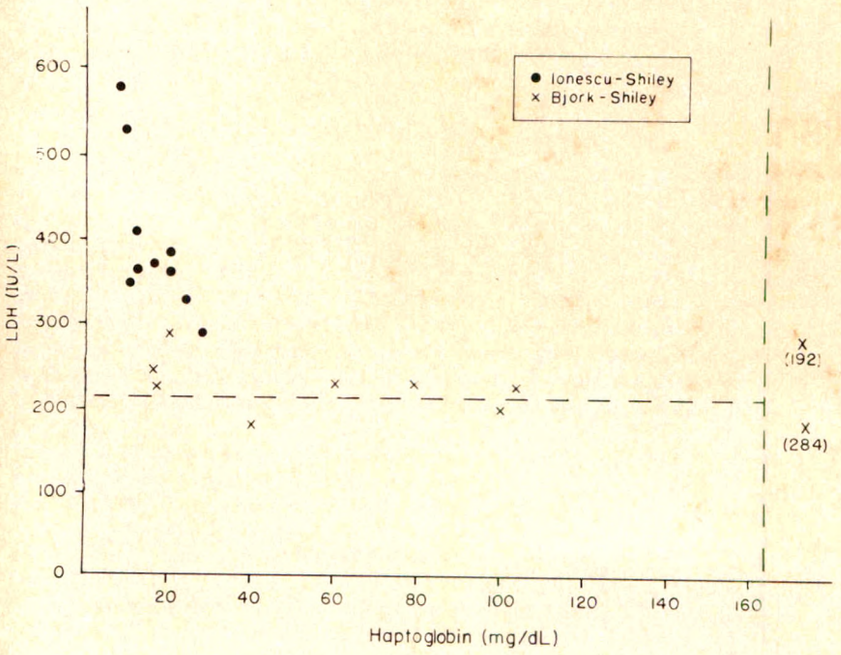

FIGURE 1. Plot diagram showing the relation between serum lactic dehydrogenase (LDH) and haptoglobin values in patients with the Ionescu-Shiley or Bjork-Shiley prosthesis. The **horizontal interrupted line** marks the upper normal range for lactic dehydrogenase, and the **vertical interrupted line** marks the lower normal range for haptoglobin.

groups (Table I). In patients with the Ionescu-Shiley valve, elevated lactic dehydrogenase values were always associated with reduced haptoglobin. In the group with the Bjork-Shiley valve haptoglobin was reduced in some patients in spite of normal lactic dehydrogenase values (Fig. 1).

Relation to valve size: The relation between valve size and values for lactic dehydrogenase and serum haptoglobin is shown in Figures 2 and 3, respectively. The degree of hemolysis as measured by either value apparently had no direct relation to valve size in any of the two prostheses evaluated.

Other signs of hemolysis: Hemoglobin concentrations (Table I) were definitely but not significantly lower in patients with an Ionescu-Shiley prosthesis. Reticulocyte counts were raised in four patients with an Ionescu-Shiley prosthesis (2.1, 2.8, 3.0, and 5.6, respectively). In the group with the Bjork-Shiley prosthesis hemolysis was so slight that reticulocyte counts were normal in all. One patient with an Ionescu-Shiley valve and a mild paravalve leak had hemosiderinuria. This patient also had the highest lactic dehydrogenase value (580 IU/liter). Bilirubin values were normal in all patients except one with an Ionescu-Shiley valve who had a marginally raised level.

Other laboratory values: The Coombs' test was negative in all patients in both groups. This finding suggests that no immune mechanism was involved in the hemolytic process. Serum glutamic oxaloacetic transaminase, serum iron, total iron binding capacity, peripheral blood smear and platelets were normal in patients in both groups.

Discussion

Hemolysis as a complication of valve replacement: Chronic intravascular hemolysis is a well-known complication of valve replacement and is probably related to the mechanical design of the prosthesis itself.[12] Measurement of serum lactic dehydrogenase (LDH, red cell isoenzyme) is a sensitive method of estimating intravascular hemolysis, and the level correlates well with the shortening of erythrocyte survival time.[13] It was elevated in all patients with an Ionescu-Shiley prosthesis, but in only two thirds of those with a Bjork-Shiley valve. In patients with the former valve, most lactic dehydrogenase values were in the range of 300 to 500 IU/liter, indicating a slightly or only moderately reduced life span of erythrocytes.[13]

Serum haptoglobin levels have been used in previous reports[7] as another index of hemolysis. In our series the haptoglobin levels were greatly decreased in all patients with the Ionescu-Shiley valve and less markedly decreased in those with the Bjork-Shiley valve.

A positive direct Coombs' test has been reported in patients after heart valve replacement. It has been suggested that an immune mechanism may be involved in some cases of hemolysis after valve replacement.[14] In our study the direct Coombs' test was negative in all cases. Therefore, it is unlikely that an immune mechanism played a role in the hemolysis detected in our series.

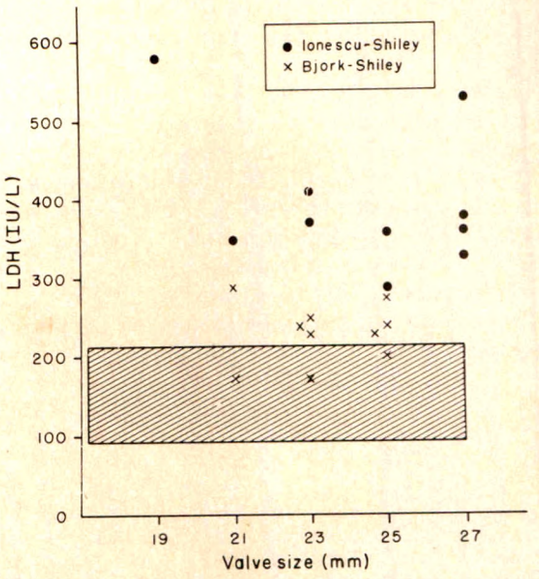

FIGURE 2. Serum lactic dehydrogenase (LDH) values related to valve size and type. The **shaded area** shows the normal range. Valve size is indicated by the valve number given by the manufacturer.

Role of size and type of valve prosthesis: There has been controversy about whether prostheses of the same type cause different degrees of hemolysis in the aortic and mitral position.[12,15] We[11] previously found that the Ionescu-Shiley prosthesis in the aortic position caused slightly greater hemolysis than the same valve in the mitral positon. Similar findings have been reported with the Starr-Edwards prosthesis.[2,15]

Hemolysis has been reported to be dependent on the size of the prosthesis.[4,16] Other investigators[1] have reported no correlation between the degree of hemolysis

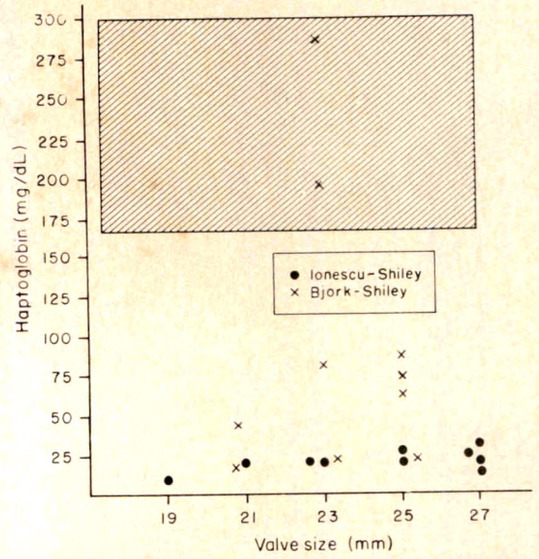

FIGURE 3. Serum haptoglobin values related to valve size and type Conventions as in Figure 2.

and the valve size. We found no direct relation between lactic dehydrogenase, haptoglobin and valve size (Fig. 2 and 3).

There is conflicting evidence concerning the value of increased serum lactic dehydrogenase as an indicator of a paravalve leak.[1,7] In our series, the highest value for lactic dehydrogenase was found in a patient with the only Ionescu-Shiley valve with a mild paravalve leak. Nevertheless, our data are inconclusive in this respect.

Implications: This hematologic study was carried out at a relatively short postoperative time interval in the group with the Ionescu-Shiley valve (mean 10.6 months). Investigators with a longer observation period of patients with other types of prostheses have reported a regression of hemolysis due to endothelialization of the valve structures.[7] If this interpretation is correct, with time one would observe a lesser degree of erythrocyte destruction with the Ionescu-Shiley xenograft than that indicated by our data.

In conclusion, this study has indicated the presence of chronic, mild intravascular hemolysis in patients with the Ionescu-Shiley prosthesis. The findings are suggestive of a significantly greater incidence and degree of hemolysis in patients with this prosthesis than in those with the Bjork-Shiley prosthesis.

Two Dimensional Echocardiographic Recognition of the Descending Thoracic Aorta: Value in Differentiating Pericardial From Pleural Effusions

WILLIAM S. HAAZ, MD
GARY S. MINTZ, MD, FACC
MORRIS N. KOTLER, MD, FACC
WAYNE PARRY
BERNARD L. SEGAL, MD, FACC

Philadelphia, Pennsylvania

The course of the descending thoracic aorta has recently been visualized with two dimensional echocardiography and its presence confirmed with contrast studies. In the parasternal short axis view, we used the location of the descending thoracic aorta to differentiate pericardial from pleural effusions in 40 patients. Sixteen patients, each with an isolated pericardial effusion, had an echo-free space between the descending thoracic aorta and left ventricular posterior wall. Nine patients, each with an isolated pleural effusion, had an echo-free space posterior to the descending aorta. Fifteen patients, each with both a pericardial and a pleural effusion, had echo-free spaces both between the descending thoracic aorta and left ventricular posterior wall and also posterior to the descending thoracic aorta. With one exception, all patients had anatomic confirmation of these findings. Forty-one patients undergoing cardiac surgery served as controls and none had a posterior echo-free space in relation to the descending thoracic aorta. At operation, no pericardial or pleural effusion was evident. The location of the descending thoracic aorta on two dimensional echocardiography serves as a valuable landmark in localizing the pericardial-pleural interface, thereby differentiating pericardial from pleural effusions.

There may be difficulty in differentiating pericardial from pleural effusions with M mode echocardiography, especially when a large posterior effusion is visualized without a concomitant anterior effusion.[1–3] M mode echocardiography may also be unreliable in differentiating a pericardial from a pleural effusion when the echo-free space extends behind the left atrium. In addition, the presence of a large left atrium may be mistaken for an effusion.[1,2,4–7]

Recently, Mintz et al.[8] visualized the position and course of the descending thoracic aorta with two dimensional echocardiography. Its presence was confirmed by means of an intravascular catheter and injection of indocyanine green or saline. Anatomically, the descending thoracic aorta lies between the pericardium and pleura (Fig. 1, left). Because the descending thoracic aorta is interposed between the pericardium anteriorly and the pleura posteriorly, it may be a useful landmark in the differentiation of posterior effusions.

The purpose of this study is therefore twofold: (1) to observe the spatial relation between the descending thoracic aorta and pericardial and pleural interfaces; and (2) to determine the value of two dimensional echocardiography in differentiating pericardial from pleural effusions by localization of the descending thoracic aorta.

Methods

Study patients: The clinical, chest roentgenographic, electrocardiographic, echocardiographic and pathologic findings in 40 patients with either pericardial, pleural or combined effusions and in 41 control patients were analyzed retrospectively. Sixteen men and 24 women had effusions. They ranged in age from

From the Likoff Cardiovascular Institute, Hahnemann Medical College and Hospital, Philadelphia, Pennsylvania. Manuscript received March 31, 1980; revised manuscript received May 28, 1980, accepted May 29, 1980.

Address for reprints: Morris N. Kotler, MD, Hahnemann Medical College and Hospital, 230 North Broad Street, Philadelphia, Pennsylvania 19102.

12 to 77 years (median age 56.5). Twenty-three men and 18 women constituted the control group. They ranged in age from 19 to 73 years (median age 56).

The patients were separated into four groups: Group I comprised 41 control patients who underwent various cardiac surgical procedures. These patients had no effusions on two dimensional echocardiography and had confirmation of the negative findings at cardiac operation.

Group II comprised 16 patients with an isolated pericardial effusion that was proved at operation in 9 patients and by pericardiocentesis in 6. One patient with congestive heart failure had echocardiographic evidence of an effusion that subsequently disappeared with diuresis. Chest roentgenography showed no pleural effusion in any of these patients.

Group III comprised nine patients with an isolated pleural effusion. The effusion was confirmed by thoracentesis in two patients, at postmortem examination in two and by chest roentgenogram in seven.

Group IV comprised 15 patients with combined pericardial and pleural effusions. Pericardial effusion was confirmed at operation in seven patients, by pericardiocentesis in seven, and by postmorten examination in one patient. Pleural effusion was confirmed by chest roentgenogram in these patients.

Echocardiography: M mode echocardiographic studies were performed in the supine or left lateral decubitus position using either a Smith-Kline Ekoline 20A ultrasonoscope interfaced with an Irex 101 Continutrace recorder or an Irex System II ultrasonoscope. Two dimensional echocardiographic studies were performed in the supine or left lateral decubitus position using a Varian V3000 or a Grumman RT-400 phased-array sector scanner. The M mode echocardiographic study consisted of a standard longitudinal sweep from the aorta to below the level of the mitral valve leaflets. The two dimensional echocardiographic study consisted of a parasternal long axis view and a series of continuous parasternal short axis views from the level of the aortic leaflets to the left ventricular apex. In the parasternal long axis view, the descending thoracic aorta appeared as a pulsatile echo-free space in the posterior atrioventricular groove.[8] In the parasternal short axis view, the descending thoracic aorta appeared as a circular or oval echo-free space at the level of the mitral leaflets and papillary muscles. At this level, the descending thoracic aorta was located directly behind the left ventricle.[8] At the level of the left atrium, the descending thoracic aorta was located directly behind the left ventricle.[8] At the level of the left atrium, the descending thoracic aorta was visualized lateral to and behind the left atrium.

During both M mode and two dimensional echocardiographic studies, gain and reject settings were adjusted for maximal far field resolution and definition. Images were recorded on videotape for later playback and analysis. This analysis was performed at real time speed, slow motion speed and stop action. The images presented on the screen were reproduced with Polaroid® photographs.

Results

Group I: The 41 control patients underwent open heart surgical procedures. These included, alone or in combination, saphenous vein-coronary bypass, ventricular aneurysmectomy, mitral or aortic valve replacement, mitral valve commissurotomy, tricuspid valve replacement and closure of atrial septal defect. Each patient was found to have physiologic amounts of fluid (less than 16 ml) or no pericardial fluid at the time of operation.

M mode studies were performed in 28 patients. Twenty-six studies showed no echo-free spaces. Two studies demonstrated the presence of a small posterior echo-free space. None of the 41 control patients had a pericardial or pleural effusion on the two dimensional study. Figure 1, right, shows the two dimensional echocardiogram of a control patient. The descending thoracic aorta was visualized directly behind the left

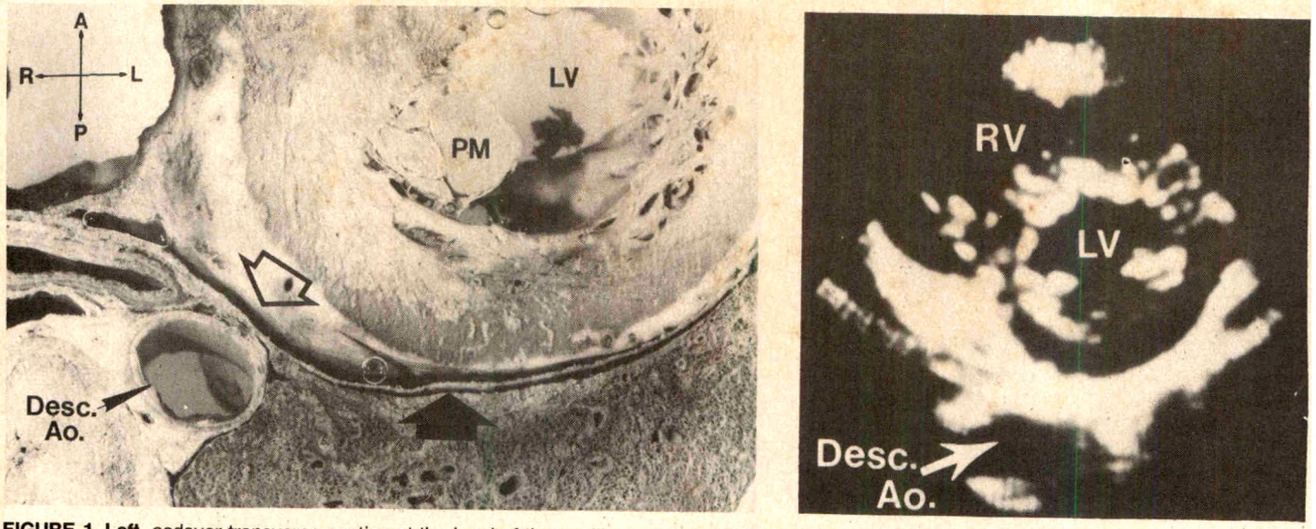

FIGURE 1. Left, cadaver transverse section at the level of the papillary muscles (PM) demonstrating the relation of the posterior pericardium (**open arrow**), left pleural space (**dark arrow**), and lung to the descending thoracic aorta (Desc. Ao.). **Right,** two dimensional echocardiographic parasternal short axis view in a normal subject. Orientation is similar to that in the panel at left. No pericardial or pleural effusion is present, and there is no separation of the descending thoracic aorta from the left ventricular (LV) posterior wall. A = anterior; L = left; P = posterior; R = right; RV = right ventricle.

ventricle in the parasternal short axis view. No echo-free space was visualized either anterior to or posterior to the descending thoracic aorta.

Group II: These 16 patients had isolated pericardial effusion due to malignancy (4 patients), congestive heart failure (3), postoperative hemopericardium (3), idiopathic causes (2), uremia (1), Dressler's syndrome (1), myxedema (1) and infection (1). Cardiomegaly was present on chest roentgenography in 14 patients. The surface electrocardiogram demonstrated low voltage (less than 0.5 mV) in the limb in only four (25 percent) of these patients.

M mode echocardiograms, performed in 15 of the 16 patients, revealed anterior and posterior echo-free spaces compatible with a pericardial effusion in 13. One patient had a large posterior echo-free space without an anterior effusion; the echo-free space extended behind the left atrium and left ventricle. One other patient had no echo-free space visualized.

All 16 patients demonstrated a pericardial effusion on the two dimensional echocardiographic study. In all, the echocardiographic pattern demonstrated in the parasternal short axis view was similar: An echo-free space was visualized anterior to the descending thoracic aorta (Fig. 2), interposed between the aorta and the left ventricular posterior wall. The normal spatial relation between the left ventricular posterior wall and descending thoracic aorta was altered. A distinct separation of these structures was present as the pericardial fluid appeared to push the heart anteriorly in the mediastinum or to push the aorta posteriorly away from the heart. No echo-free space was present behind the descending thoracic aorta.

Group III: These nine patients had isolated pleural effusion due to post-thoracotomy status (four patients), congestive heart failure (three), malignancy (one) and radiation therapy (one). Five patients demonstrated cardiomegaly, and seven patients demonstrated pleural effusion on chest roentgenography. The surface electrocardiogram showed low voltage in two patients.

M mode echocardiograms, performed in eight of the nine patients, revealed a posterior echo-free space without an anterior echo-free space in five; three patients had no posterior echo-free space.

The two dimensional echocardiographic study demonstrated a posterior pleural effusion in all nine patients. In the parasternal short axis view, all patients had an echo-free space visualized posterior and lateral to the descending thoracic aorta (Fig. 3). The fluid was therefore localized behind the descending aorta and left ventricular posterior wall. The normal spatial relation between the descending thoracic aorta and left ventricular wall was preserved. No echo-free space was visualized anterior to the descending thoracic aorta.

Group IV: These 15 patients had combined pericardial and pleural effusions due to postoperative status (3 patients), congestive heart failure (3), uremia (3), radiation therapy (2), malignancy (2), drug therapy (1) and benign tumor (1). On chest roentgenography 8 patients demonstrated cardiomegaly, and all 15 patients

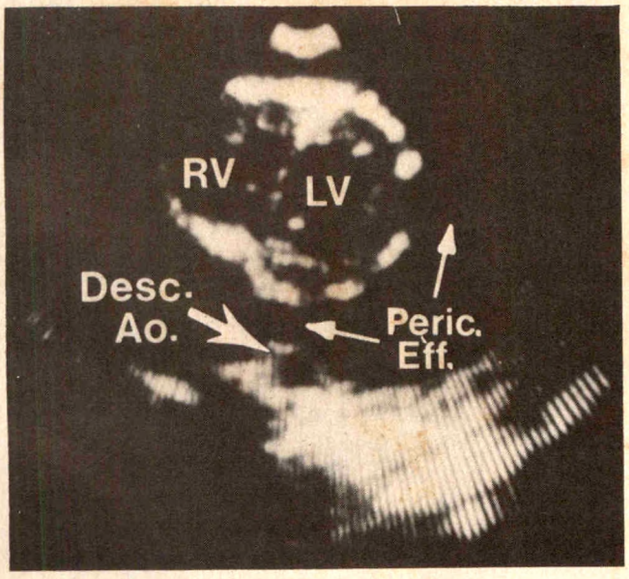

FIGURE 2. Two dimensional echocardiographic parasternal short axis view in a patient with a posterior pericardial effusion (Peric. Eff.). The pericardial effusion appears as an echo-free space anterior to the descending thoracic aorta (Desc. Ao.). A distinct separation of the descending aorta and left ventricular (LV) posterior wall is present. RV = right ventricle.

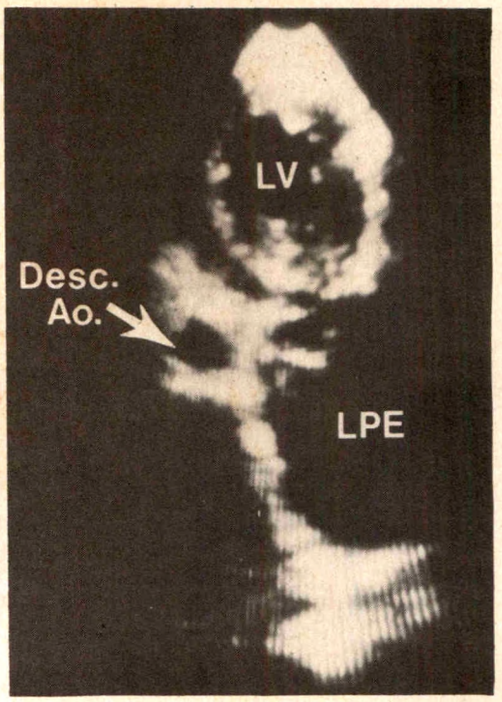

FIGURE 3. Parasternal short axis view in a patient with an isolated left pleural effusion (LPE). The effusion appears as an echo-free space posterior and lateral to the descending thoracic aorta (Desc. Ao.). Anterior to the aorta the left ventricular (LV) posterior wall is seen. It consists of a dense pericardium separated from the endocardium by a relatively echo-free zone of myocardium. This should not be misinterpreted as a pericardial effusion.

had a pleural effusion. The surface electrocardiogram demonstrated low voltage on the limb leads of four patients.

M mode echocardiograms, performed in all 15 patients, revealed definite pericardial effusion in 12 (80 percent; however, 3 patients (20 percent) demonstrated a posterior echo-free space that could not be differentiated from a pleural effusion.

The two dimensional echocardiographic study demonstrated both pericardial and pleural effusions in all 15 patients. The echocardiographic pattern in all patients was similar: In the parasternal short axis view, an echo-free space was visualized both anterior to and posterior and lateral to the descending thoracic aorta (Fig. 4). Therefore, features of both pericardial and pleural effusions were present. The spatial relation between the aorta and left ventricular posterior wall was altered as in patients in Group II. The heart appeared to be pushed anteriorly or the descending thoracic aorta to be pushed posteriorly by the echo-free space. As in patients in Group III there was also an echo-free space seen posterior and lateral to the descending thoracic aorta.

Discussion

The clinical utility of M mode echocardiography in detecting pericardial effusion was recognized in the 1960s by Feigenbaum et al.[9–12] More recent data by Horowitz et al.[13] showed that M mode echocardiography is extremely sensitive and can detect as little as 20 ml of pericardial fluid.

Limitations of M mode echocardiography in diagnosis of pericardial effusion: Certain pitfalls have been recognized in the diagnosis of a pericardial effusion by M mode echocardiography.[2,8] Large pleural effusions, pulmonary infiltrates, a large left atrium, and tumors have all been reported to simulate a pericardial effusion in the M mode echocardiogram.[1,2,7,14–17] Although fluid visualized posterior to the left atrium is generally diagnostic of a pleural effusion, the left oblique sinus (pericardial reflection over the great vessels) is a potential space for an accumulation of pericardial fluid. Several investigators[1,2,5,6] have demonstrated the presence of a pericardial effusion behind the left atrium with M mode echocardiography. The descending thoracic aorta itself has been visualized behind the left ventricular posterior wall as an echo-free space, thus simulating a pericardial effusion.[8] Conversely, pericardial fluid may be present and yet be undetected in the M mode echocardiogram because of a loculated pericardial effusion or too medial a transducer angulation.[2,3,5,6,18,19]

In our study, 83 percent of the M mode studies were diagnostic in patients with a pericardial effusion. In 17 percent there was some difficulty in differentiating between a pericardial and pleural effusion.

Advantages of two dimensional echocardiography: The presence of a pericardial effusion, superior to the atrioventricular groove and visualized behind the left atrium, has been demonstrated with two-dimensional echocardiography by Martin et al.[4] All of their patients with a quantitatively large effusion had a posterior echo-free space behind the left atrium. Two dimensional echocardiography has also been reported to be of clinical value in detecting an isolated pericardial effusion when the M mode study was equivocal.[18] Two dimensional echocardiography, as compared with M mode echocardiography, facilitates study of posterior structures because of improved spatial orientation.[4,8] Only recently has it been appreciated that the descending thoracic aorta could be consistently visualized in a posterior location with two dimensional echocardiography.[8,19–21]

In this study, the descending thoracic aorta was a valuable landmark in differentiating pericardial from pleural effusions. The left parasternal short axis ap-

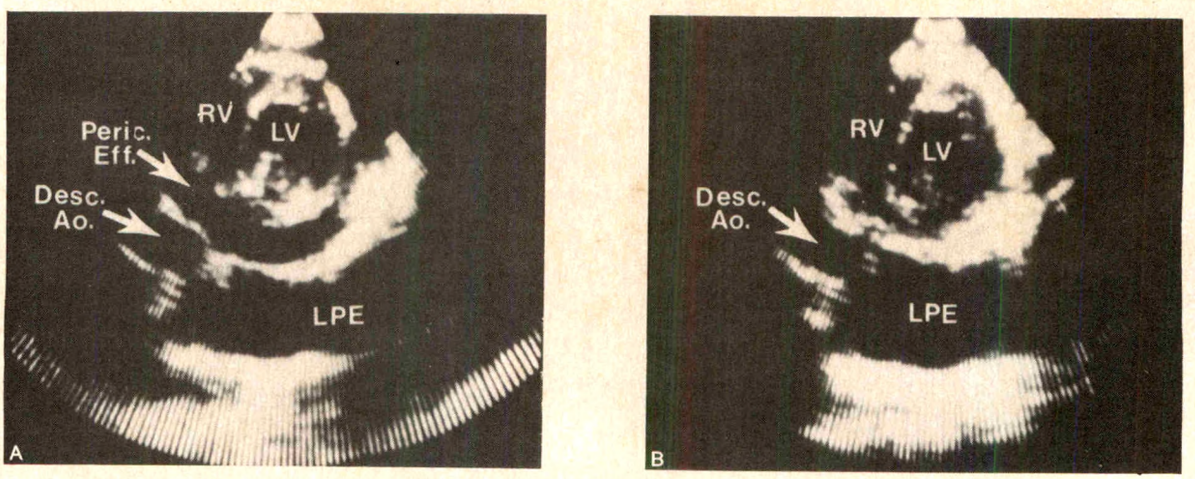

FIGURE 4. Parasternal short axis views in a patient with both a posterior pericardial (Peric. Eff.) and left pleural effusion (LPE). **A**, the effusions appear as echo-free spaces both anterior and posterior and lateral to the descending thoracic aorta (Desc. Ao.). There is a separation between the descending aorta and left ventricular (LV) posterior wall. **B**, after pericardiocentesis there is disappearance of the anterior echo-free space; the left pleural effusion remains. RV = right ventricle.

peared to be most useful for localizing the effusion. In the parasternal short axis view, pericardial effusion appeared as an echo-free space interposed between the descending thoracic aorta and the left ventricular posterior wall. A pleural effusion was visualized as an echo-free space posterior and lateral to the descending thoracic aorta. Combined pericardial and pleural effusions were visualized as echo-free spaces both anterior to and posterior and lateral to the descending thoracic aorta. The spatial relation between the descending thoracic aorta and left ventricular posterior wall that exists in the absence of any type of effusion was altered in the presence of a pericardial effusion. The descending thoracic aorta was not seen in its normal position adjacent to the left ventricular wall, but was separated because of effusion's effect of pushing the heart anteriorly or the descending thoracic aorta posteriorly.

Both pericardial and pleural effusions accumulate initially in the most dependent portion of the pericardial and pleural cavities; therefore, a posterior echo-free space is usually present posteriorly before an anterior echo-free space in a supine echocardiographic study.[4,6,22] Gravity maximizes the space between the descending thoracic aorta and both the pericardial and pleural interfaces. Thus, early detection of a posterior pericardial effusion with the M mode technique would also apply to two dimensional echocardiography. This would suggest that the echocardiographic patterns described should be sensitive and should occur even with small effusions.

Clinical implications: The patients who formed the basis of our study were selected as patients who demonstrated a distinct two dimensional echocardiographic pattern and who had anatomic confirmation of their echocardiographic findings. Therefore, by design, most of our patients had large effusions. The determination of the exact sensitivity and specificity of these findings awaits additional prospective study. However, we believe that the intimate relation of the descending thoracic aorta to the left ventricular posterior wall, pericardium and pleura is a valuable landmark in detecting and differentiating pericardial from pleural effusions.

Histologic and Ultrastructural Features of Normal Human Parietal Pericardium

Morphologic studies of normal anterior parietal pericardium from seven patients revealed this tissue to be composed of three layers: (1) the serosa, consisting of a surface layer of mesothelial cells and a narrow submesothelial space, (2) the fibrosa, containing variously oriented layers of collagen fibrils and small elastic fibers, and (3) the epipericardial connective tissue layer, containing mainly large coarse bundles of collagen and forming part of the pericardiosternal ligament. Scanning electron microscopic examination is most useful for study of the surface features of pericardial mesothelial cells, which have single cilia and are covered with microvilli. The latter bear friction and increase the surface area for fluid transport. Junctional complexes between adjacent mesothelial cells consist of desmosomes, which reinforce intercellular adhesion and zonulae occludentes, which form permeability barriers. Actin-like filaments (50 Å in diameter) are present in microvilli and in immediately subjacent regions of the cells; these filaments mediate changes in cell shape. Intermediate filaments (100 Å in diameter) are associated with desmosomes and form bundles in the perinuclear regions; these filaments provide structural support to the cytoplasm.

Although pericardial disease constitutes an important aspect of cardiovascular pathology, little information is available on the fine structure of the pericardium in health or in disease. No scanning electron microscopic studies of pericardium have been reported, and the only transmission electron microscopic observations made on this tissue[1–5] have been essentially limited to the mesothelial cell layer. A new stimulus for studying the ultrastructural features of the pericardium has been provided by the clinical use of parietal pericardium for bioprosthetic heart valves and for patches to repair various cardiovascular lesions. Detailed knowledge of the morphologic characteristics of normal pericardium is essential to evaluate the long-term durability and usefulness of these products. This study describes histologic and transmission and scanning electron microscopic observations made on normal human parietal pericardium.

Methods

Patients: Morphologic studies were made of parietal pericardium from seven patients, six male and one female, ranging in age from 10 to 69 years (average 47), who underwent cardiac operations in the National Heart, Lung, and Blood Institute. None of the patients had a history of pericarditis. In each patient the pericardial cavity at operation contained normal amounts of fluid and the pericardium was grossly and histologically normal, with no thickening or inflammation. Small pieces of pericardium were removed from the anterior (ventral) portion of the pericardial sac, pinned on to a corkboard at their in situ dimensions, with the serosal surface up, and placed in a solution of 3 percent glutaraldehyde in 0.1 *M* phosphate buffer, pH 7.2. The tissues were then washed with several changes of 5 percent sucrose in 0.1 *M* phosphate buffer, pH 7.2, and cut into smaller pieces for histologic and ultrastructural study.

Histologic and electron microscopic preparation: For histologic study, tissues were embedded in paraffin and in glycolmethacrylate plastic medium. Paraffin sections were stained with hematoxylin-eosin and alkaline toluidine blue. For scanning electron microscopy, tissues were dehydrated, critical point-dried, coated with gold-palladium and examined at an accelerating voltage of 20 kV. For transmission electron microscopy, tissues were dehydrated with a graded series of ethanols and propylene oxide and embedded in Maraglas®[6] with use of flat embedding molds to obtain proper orientation of the tissue. Ultrathin sections were stained with uranyl acetate and lead citrate. Selected sections were stained according to the method of Kajikawa et al.[7] for the selective demonstration of elastic fibers.

Results

Histology

The parietal pericardium (Fig. 1, A to C) was composed of three layers: the serosa, the fibrosa, and an outer layer of epipericardial connective tissue. The serosa consisted of a surface layer of mesothelial cells and of a narrow submesothelial space (about 2 μ in width) that separated the mesothelial cells from the fibrosa, the underlying layer. The population density of mesothelial cells varied from one area to another, even when the normal dimensions of the tissue were maintained during fixation; under these conditions, the mesothelial cells appeared greatly flattened and showed mild bulging in the region of the nuclei. Microvilli were demonstrable by light microscopic study of sections of plastic-embedded tissue (Fig. 1D). When the pericardium was dropped into the fixative without maintaining its in vivo dimensions, the mesothelial cells appeared thicker and less flattened, and their nuclei showed more prominent bulging. The fibrosa was composed of connective tissue cells, small vessels, compactly arranged collagen (Fig. 1A) and small, inconspicuous elastic fibers (Fig. 1B). The epipericardial connective tissue layer contained collagenous and elastic fibers, adipose tissue cells, neural elements and blood vessels. A few mast cells, lymphocytes and histiocytes were encountered in this layer and in the fibrosa.

Several layers of collagenous bundles were recognizable in the fibrosa (Fig. 1A). The bundles immediately subjacent to the mesothelial cells appeared oriented along the cepha-

lad-caudad axis. Deeper layers showed more of a weaving pattern, with collagen bundles running in various directions. This arrangement was examined in detail by using a polarized light microscope to demonstrate the birefringence of collagen (Fig. 1C). Elastic fibers were usually small (less than 2 μ in diameter), and frequently were oriented perpendicular to the collagen bundles. The elastic fibers immediately subjacent to the mesothelium were smaller than were those in deeper areas of the fibrosa. Embedded in the connective tissue of the fibrosa were slender, greatly elongated connective tissue cells with long, thin nuclei and scanty cytoplasm. Some of these cells had fine cytoplasmic processes that extended parallel to the collagen bundles. Vessels penetrated, usually in an oblique manner, from the epipericardial layer toward the serosa, and frequently extended up to a distance of only 8 μ from the surface. Some vascular channels were dilated and thin-walled and probably represented lymphatics. Some of the collagen bundles in the epipericardial connective tissue layer were very coarse and provided connections between the pericardium and the anterior mediastinum (pericardiosternal ligament).

Scanning Electron Microscopy

On examination at low magnification, the serosal surfac of the pericardium appeared completely covered by meso thelial cells, which were polygonal in outline and did not sho a pattern of preferential orientation. The surfaces of th mesothelial cells contained numerous microvilli that measure up to 3 μ in length and 0.1 μ in width. In many areas, the mi crovilli completely covered the surfaces of the cells (Fig. 2A) In other areas, the microvilli tended to be concentrated in th central portions of the cells, leaving relatively smooth area in their peripheral portions. Occasionally, microvilli wer concentrated in peripheral regions of some cells, the centra areas of which appeared smooth (Fig. 2B). Other cells hac either knob-like protrusions or cup-like depressions in th central areas of their surfaces. Single cilia, which were thicke and considerably longer than microvilli, were also found i some cells. Observations by transmission electron microscop confirmed that these structures were cilia.

Areas of intercellular junctions were visualized as discret narrow ridges (Fig. 3A). No intercellular spaces were presen

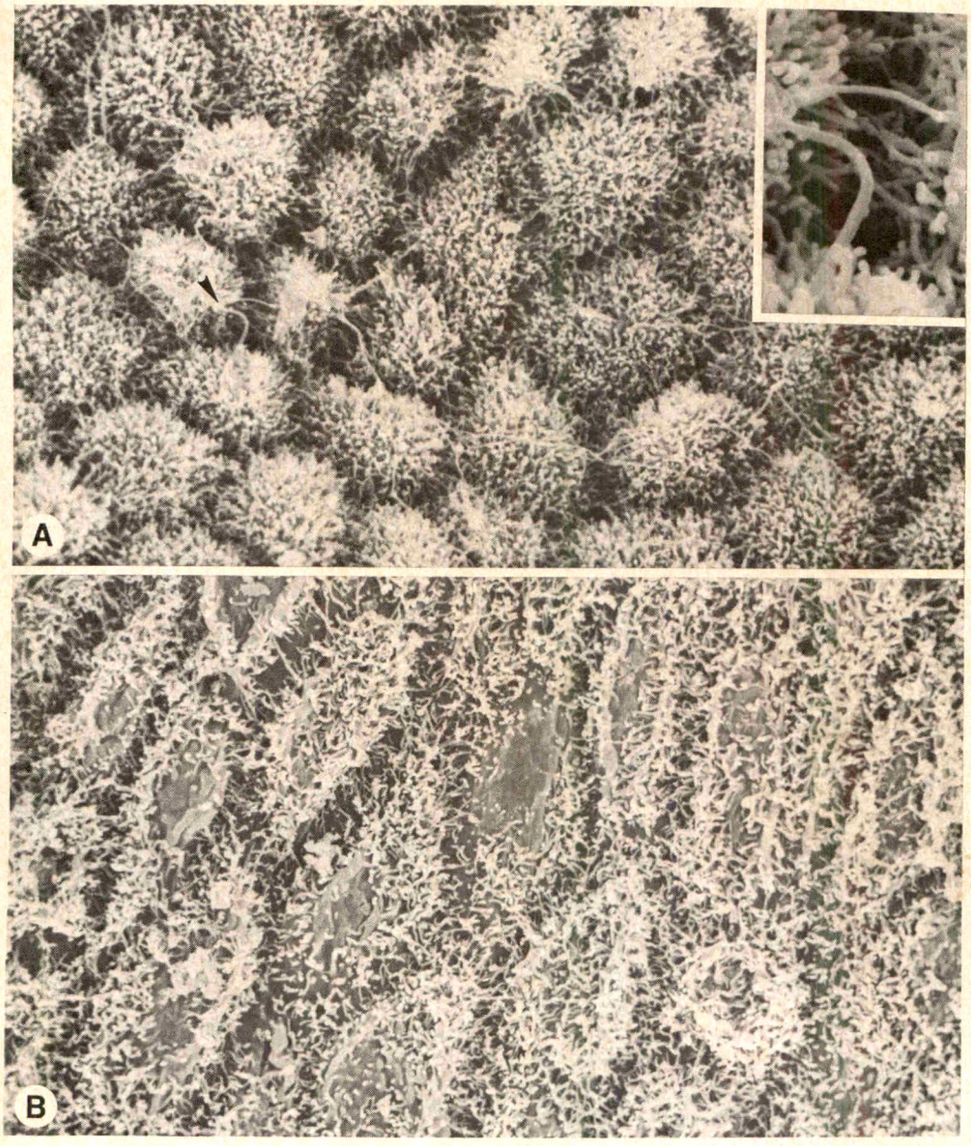

FIGURE 2. Scanning electron micrographs of human parietal pericardium. **A**, view of area in which the serosal surfaces of the mesothelial cells are completely covered by microvilli. Cilia (**arrowhead**), which are thicker and considerably longer than microvilli, are also distinguishable. **Inset** shows higher magnification view of cilium indicated by **arrowhead. B,** view of area in which microvilli tend to form rings near peripheral portions of the cells, leaving smooth central portions. (Magnifications: **A**, ×3,800 (**inset,** ×10,000); **B**, ×3,400, all reduced by 27 percent.)

between adjacent mesothelial cells. In areas from which the mesothelial cells had been accidentally detached during the course of specimen preparation, the serosal surface was composed of bundles of collagen fibrils (Fig. 3B). These bundles had a wavy appearance and were covered by a layer of material without discernible substructure. This layer (Fig. 3C) corresponded to the basal lamina of the mesothelial cells. Individual collagen fibrils were clearly evident within these superficial bundles only when the serosal surface had been more strongly abraded (Fig. 3, D and E).

The mediastinal surface of parietal pericardium (*Fig. 3F*) contained large collagen bundles that coursed in various directions, measured up to 15 μ in diameter and projected above the surface. These bundles, which were much larger than those subjacent to the serosal surface, imparted a characteristic appearance to the mediastinal surface. Subjacent to these bundles was a more homogeneous layer of collagen bundles, which were smaller and more tightly packed. Individual fibrils were evident within these bundles only when they had been disrupted.

Transmission Electron Microscopy

The mesothelial cells (*Fig. 4, A to D*) formed a continuous monolayer, but in some areas the overlap between adjacent cells was considerable, even to the extent that stacked profiles of three cells could be found (Fig. 4C). A distinct glycocalyx or fuzzy coating (less than 100 Å in thickness) was evident on the external leaflet of the plasma membrane in the luminal or serosal surface (Fig. 4B). Microvilli measured 0.1 μ in diameter and contained fine filaments that were oriented longitudinally and measured 50 Å in diameter (Fig. 4B). These filaments were also present, in a less organized arrangement, in areas of cytoplasm immediately subjacent to the microvilli (Fig. 5, A to C). Cilia were encountered occasionally and were composed of rootlets, a basal body and a core of regularly arranged microtubules (Fig. 4D). Pinocytotic vesicles were present only in small numbers along the luminal surfaces. The lateral surfaces of the mesothelial cells were closely interdigitated and apposed over most of their course (Fig. 4C, 5, B and C and 6, A and B). Specialized intercellular junctional

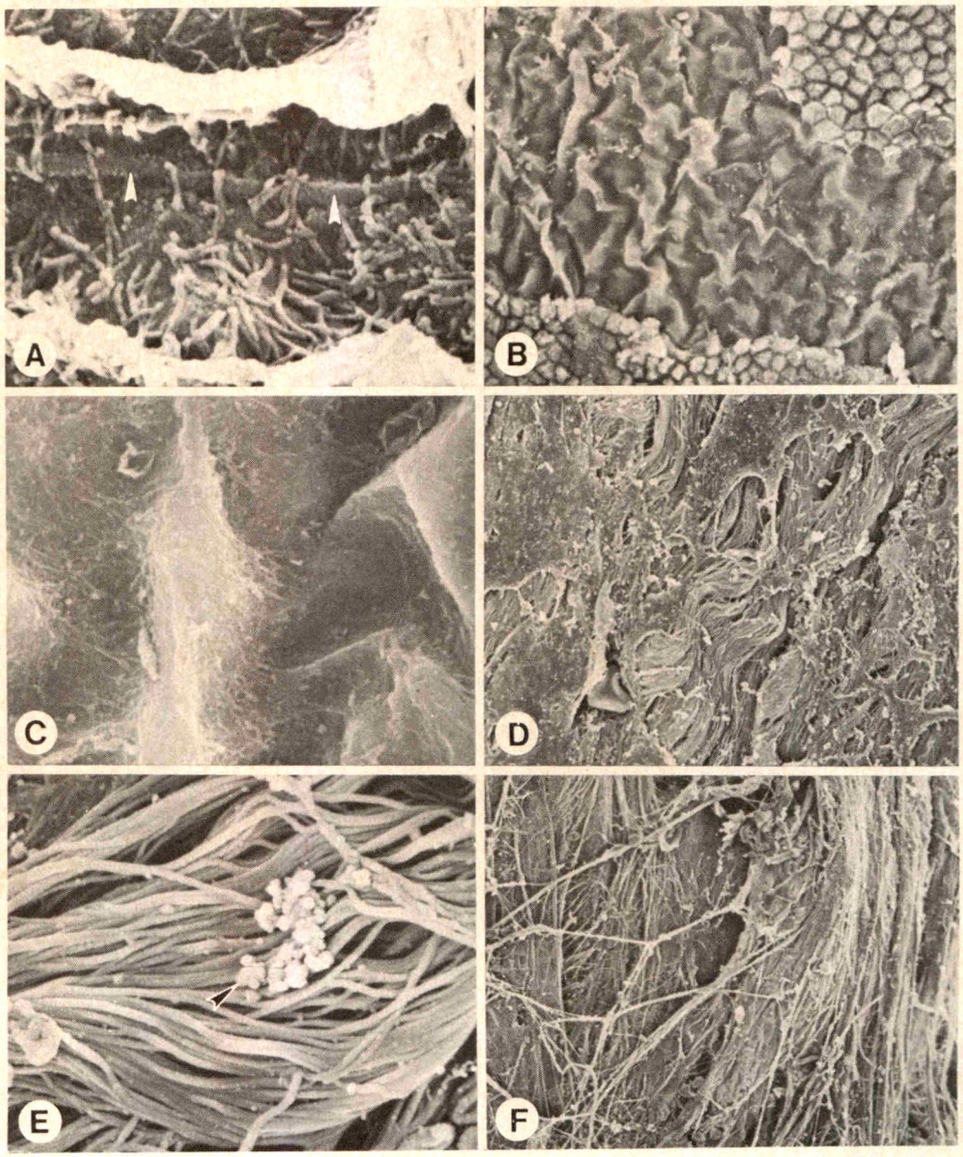

FIGURE 3. Scanning electron micrographs of human parietal pericardium. **A**, intercellular junction appears as a slightly elevated ridge (**arrowheads**). **B**, area of partial denudation of mesothelial cell layer. Some mesothelial cells remain (**bottom and upper right**). Surface of denuded area has a wavy configuration that reflects arrangement of underlying collagen. **C**, high magnification view of area similar to that shown in **B**. The surface is relatively smooth; it is composed of basal laminar material, and collagen fibrils are not evident. **D**, area of surface from which the mesothelial cells have been completely denuded and the basal lamina has been partially removed, exposing underlying bundles of collagen fibrils. **E**, high magnification view of center of area shown in **D**. Collagen fibrils are seen as discrete units, together with some cellular debris. **F**, low magnification view showing large coarse collagenous bundles in the pericardial surface that faces the sternum. (Magnifications: **A**, ×10,000; **B**, ×300; **C**, ×3,000; **D**, ×1,000; **E**, ×10,000; **F**, ×100, all reduced by 27 percent.)

structures along these lateral surfaces were few in number and consisted of zonulae occludentes (Fig. 5, B and C and 6A) and desmosomes (Fig. 5D and 6A). The apposed lateral plasma membranes were separated by an intercellular space of about 200 Å in width; however, in areas of zonulae occludentes, the apposed outer leaflets of the two plasma membranes appeared as single lines. The space between adjacent cells also showed focal dilatations of up to 1 μ in width. Some of these dilatations contained microvilli (Fig. 6A); others were filled by basal lamina material (Fig. 6B). Zonulae occludentes measured up to 0.4 μ in length and typically were present at the points where the areas of apposition terminated at the luminal surfaces (Fig. 5B and C). Zonulae occludentes were less commonly present near the abluminal surface. Desmosomes were small (up to 0.5 μ in length) and were the sites of insertion of bundles of cytoplasmic filaments (Fig. 5D and 6A). These filaments measured 100 Å in diameter; therefore, they were larger than those associated with the microvilli. In some cells, the 100 Å filaments formed bundles that coursed around the nuclei (Fig. 6C). In addition to microvilli, the luminal surfaces of the mesothelial cells showed irregularly shaped invaginations that extended for variable distances into their cytoplasm (Fi 5A).

The basal surfaces of the mesothelial cells showed rel tively minor folds and moderate numbers of pinocytotic ve icles; however, they did not exhibit cytoplasmic processes th projected deeply into the underlying connective tissue. some areas, the basal surface had a clear, well defined bas lamina, that measured up to 500 Å in width and was subd vided into a lamina densa and a lamina clara (Fig. 4C). Hov ever, in most areas the basal lamina material extende without any zones of discontinuity, from the basal surfac of the cells through the submesothelial space and into th uppermost layer of collagen fibrils in the fibrosa (Fig. 6B an 7A). The extent of irregularity of the basal surfaces of th mesothelial cells appeared to be related to the degree of fla tening and elongation of the cytoplasm. Tubular invaginatio of cytoplasm were also present along the basal surfaces of th mesothelial cells; some of these invaginations contained bas laminar material (Fig. 5D). Hemidesmosomes, anchoring f brils or other structures that can attach cells to the underlyir connective tissue were not present in parietal pericardium

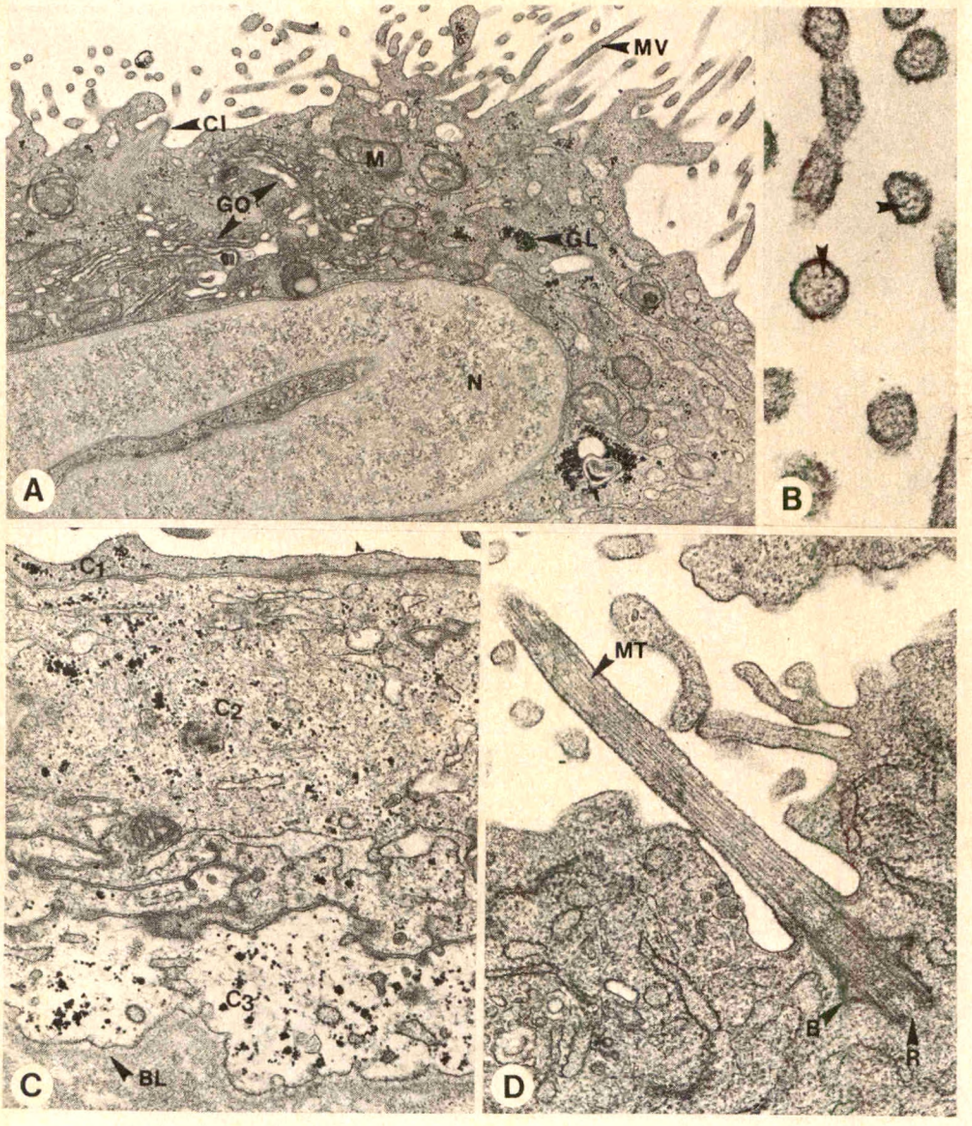

FIGURE 4. Transmission electro micrographs of the surfaces pericardial mesothelial cells. **A** perinuclear region of mesotheli cell, showing nucleus (N), prom nent Golgi complexes (GO), glyc gen granules (GL), mitochondria (M microvilli (MV) and part of the bas of a cilium (CI). **B**, cross sections microvilli showing the trilamina membrane, the fuzzy coat on th surface, and the core filament (**arrowheads**). **C**, area of overlap three cells. At the top, a very thir flattened cell with dense cytoplasr is present (C_1). Subjacent to thi cell, there is a second cell with les dense cytoplasm (C_2). A third ce (C_3) with clear cytoplasm is found the bottom, overlying a discret basal lamina (BL). **D**, longitudina section through a cilium, showing it basal body (B), rootlets (R) and th microtubules (MT) in its main seg ment. Note the microvilli and th cisterns of endoplasmic reticulun adjacent to the cilium. (Magnifica tions: **A**, ×20,400; **B**, ×97,000; **C** ×27,000; **D**, ×38,000, all reduce by 27 percent.)

The cytoplasm of the mesothelial cells (Figs. 4, A and C, 6, B and C) contained: small numbers of mitochondria and lysosomes; large, well developed Golgi complexes composed of stacks of parallel cisterns; moderate numbers of multivesicular bodies; cytoplasmic filaments of two types: actin-like (40 to 75 Å in diameter) and cytoskeletal (100 Å in diameter) as described earlier; a few microtubules; and variable numbers of glycogen granules, lipid droplets and cisterns of rough-surfaced endoplasmic reticulum. Indentations and folds were present in the nuclear membranes of some cells. The nuclei contained a moderately prominent nucleolus. In one of the seven patients, the spaces between the inner and outer nuclear membranes contained small clusters of vesicles (Fig. 6C).

The cytoplasmic density of mesothelial cells varied considerably (Fig. 4C). Some cells appeared dense, primarily because of their high content of free ribosomes and cisterns of endoplasmic reticulum; other cells had few of these components, and for this reason they appeared much more electron-lucent. These differences appeared to represent a continuum of variations rather than two or more distinct cell types. In addition, some cells had clear areas of cytoplasm associated with apparent displacement of organelles to one side of the cell. These areas of cytoplasm showed poor tissue preservation and were regarded as being sites of fixation artifacts.

The fibrosa contained collagen (Fig. 7A), elastic fibers (Fig. 7B) and flattened cells (Fig. 7C), which in many ways resembled the veil cells described in arterial adventitia.[8] These cells contained few organelles and had long cytoplasmic processes, in which a few mitochondria, occasional cisterns of rough-surfaced endoplasmic reticulum and sparse, actin-like and cytoskeletal filaments were present.

The collagen fibrils showed their usual periodic banding. Their diameter ranged from 500 to 1,500 Å and averaged 850 Å. They were arranged parallel to the surface and they formed tightly packed bundles or sheets that were oriented in different directions. The arrangement of the collagen fibrils was very compact, and in some areas the direction of adjacent bundles or sheets of collagen changed quite sharply (Fig. 7A). In most areas, the amount of interfibrillary material was small and no spicules (that is, such as those present[9] in arterial walls) of proteoglycan material were seen. In most areas, the collagen

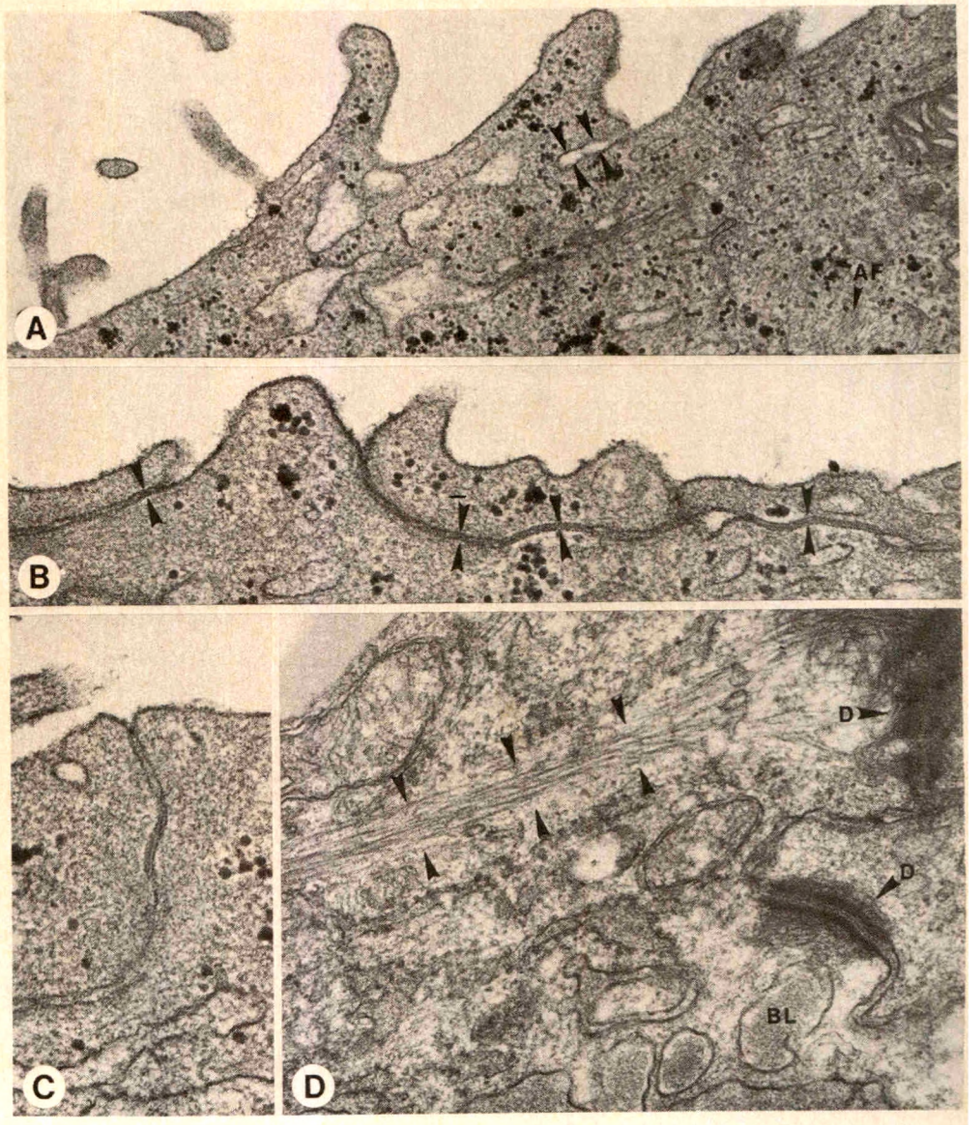

FIGURE 5. Surface features and junctional complexes of pericardial mesothelial cells. **A**, irregular surface folds are associated with invaginations (**arrowheads**) and differ clearly from microvilli (**left**). Actin-like cytoplasmic filaments (AF) are present in the cytoplasm. **B**, zonulae occludentes (**arrowheads**) form permeability seal between adjacent mesothelial cells. **C**, high magnification view of zonula occludens similar to those shown in **B**. Note transport vesicle at left of junction. **D**, typical desmosomes (D) are associated with bundles of intermediate (100 Å in diameter) filaments (**arrowheads**). Cytoplasmic invaginations containing basal lamina material (BL) are present along the basal surface of the cell. (Magnifications: **A**, ×41,000; **B**, ×73,000; **C**, ×88,400; **D**, ×60,300, all reduced by 27 percent.)

fibrils were intimately associated with a network of delicately fibrillar material of undetermined nature.

Elastic fibers (*Fig. 7, B and C*) ranged from 0.3 to 0.7 μ in diameter and showed their two usual components: the centrally located elastin material, which was selectively stained black by the Kajikawa method, and the peripherally located microfibrils (130 to 150 Å in diameter). Small bundles of microfibrils were occasionally found between collagen fibrils but without being associated with elastin material.

Discussion

The observations in this study demonstrate the complexity of the organization of the various structural components of human parietal pericardium and illustrate the range of adaptations that this tissue has developed in order to perform its functions. These adaptations were evident in the mesothelial cell layer (serosa) as well as in the underlying connective tissue layer (fibrosa).

Mesothelial Cells

Microvilli and cilia: The most striking morphologic feature of pericardial mesothelial cells was the presence of microvilli and cilia on the serosal or luminal surfaces. Microvilli were extremely numerous and covered most of the luminal surface area. These microvilli were more numerous than those in peritoneal mesothelial cells[10–13] and resembled those in pleural mesothelial cells.[14,15] Microvilli are also present in mesotheliomas.[16,17] We attribute at least two functions to microvilli: (1) They provide pericardium with specialized friction-bearing surfaces, and (2) they increase the cell surface area available for fluid transport.

The cilia found in pericardial mesothelial cells differed from microvilli in size and substructure. Cilia are capable of motility, often in the form of a sweeping motion. The motility of cilia is mediated through the side arms on their microtubules.[18] In contrast to these

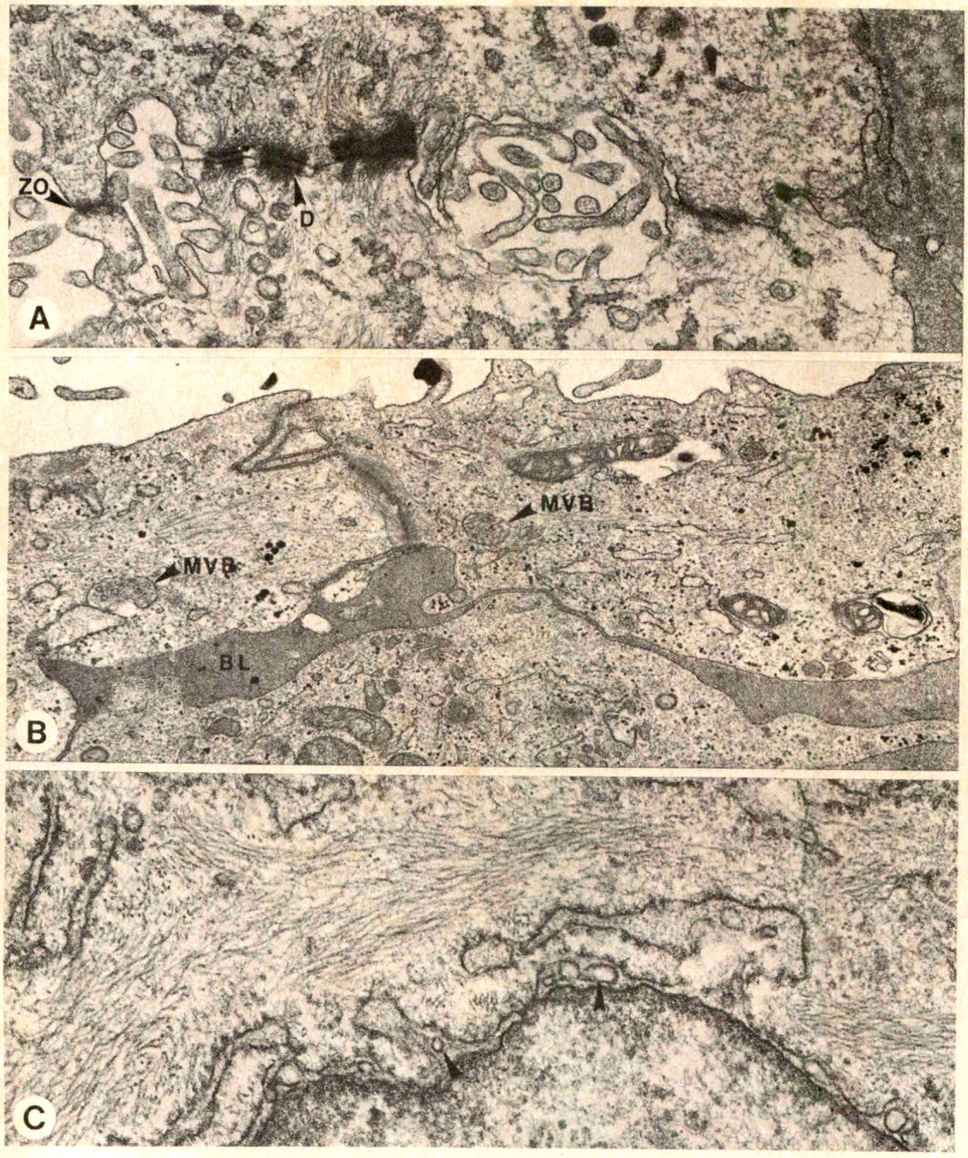

FIGURE 6. Junctions and cytoplasmic filaments of pericardial mesothelial cells. **A**, junction between two cells extends from luminal surface (**left**) to basal surface (**right**). A zonula occludens (ZO) is located at the luminal end, and several desmosomes (D) associated with 100 Å filaments are found in adjacent regions of the junction. Note presence of microvilli in two areas of widening of the intercellular space. **B**, intercellular space in area of overlap between adjacent cells is filled by basal lamina material (BL). Note multivesicular bodies (MVB) in two of the cells. **C**, bundles of 100 Å filaments course in vicinity of nucleus of mesothelial cell. Small vesicles (**arrowheads**) are located in the space between the inner and outer nuclear membranes. (Magnifications: **A**, ×31,900; **B**, ×24,300; **C**, ×74,400, all reduced by 27 percent.)

features, microvilli lack a basal body and microtubules and contain only a core of longitudinally oriented microfilaments. Microvilli also undergo changes in shape that are presumably mediated by their core filaments. These filaments insert into the tips of the microvilli and constitute a network that extends below their base. In intestinal epithelial cells the core filaments associated with microvilli have been shown to be composed of actin[19–21] and to bind heavy meromyosin (a property typical of actin filaments) with specific patterns of orientation of the resulting "arrowhead" complexes.[19,20] The passive changes in shape pericardial mesothelial cells undergo with cardiac systole and diastole are not known. Nevertheless, it is clear that these cells possess the subcellular components needed to alter actively the configuration of their luminal surfaces.

Transport systems: The luminal and basal surfaces of pericardial mesothelial cells had irregularly shaped invaginations of the plasma membranes as well as multivesicular bodies and coated and uncoated vesicles. These structures are known to function in transport of fluid and protein materials. It is reasonable to postulate that the two types of transport systems existing in other cells[22] are also present in pericardial mesothelium: transport through the intercellular spaces and transport across the cytoplasm by means of vesicles. The latter would form by invagination of the plasma membrane at one surface, pinch off, move across the cytoplasm, fuse with the plasma membrane at the opposite surface of the cell, and then discharge their content into the extracellular space. The relative importance of these two mechanisms in pericardial mesothelial cells is unknown. Studies of pericardial transport functions[23–26] have shown that relatively small molecules can be removed from the pericardial cavity, presumably by way of subepicardial capillaries, and that larger molecules and discrete particles (colloidal gold, colloidal carbon) are removed extremely slowly. Entry into lymphatics from the pericardial cavity seems to occur with the greatest difficulty and very slowly.[23] The findings of these functional studies, indicating very slow removal of macromolecules from the pericardial cavity, are in accord with the observations of Kluge and Hovig[3,4] and of the present study, in which zonulae occludentes were demonstrated in the intercellular junctions connecting pericardial mesothelial cells. Such junctions, which typically were present near the two terminations of the zone of cell to cell apposition at the basal lamina and at

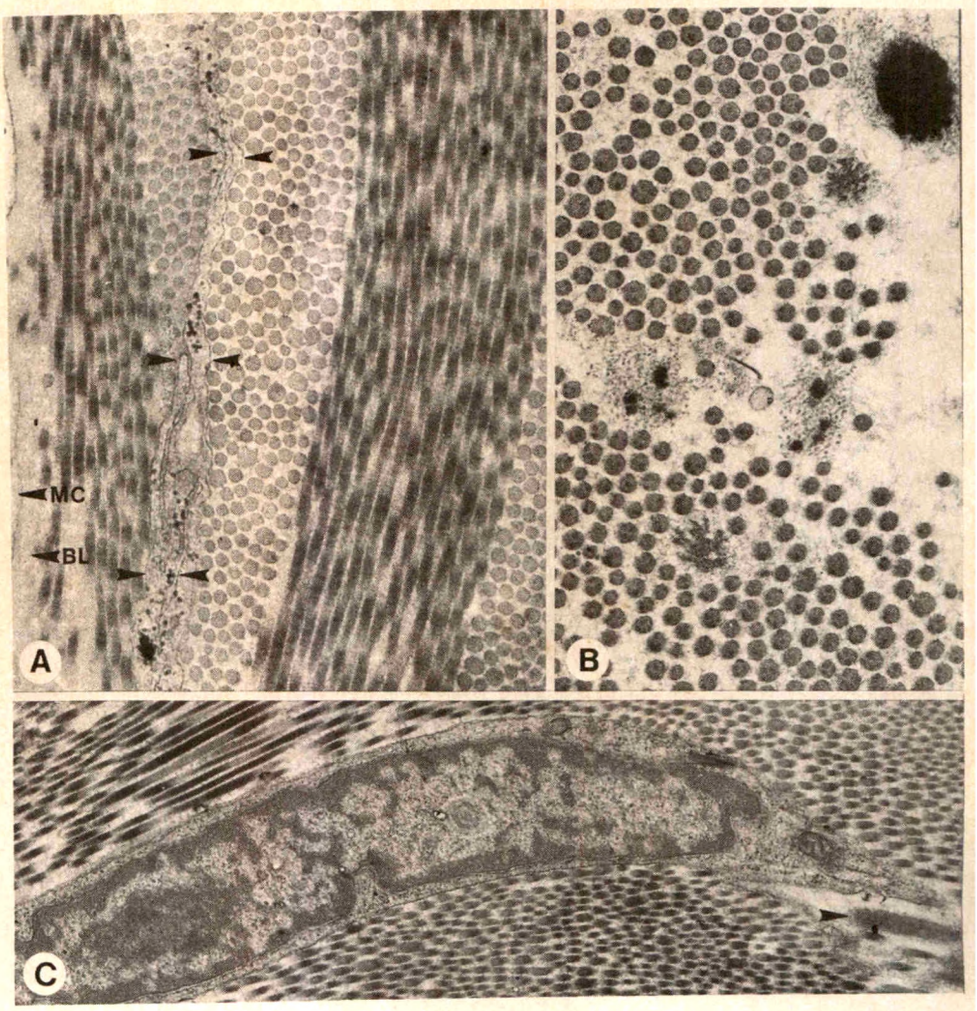

FIGURE 7. Transmission electron micrographs of pericardial connective tissue. **A**, section through submesothelial area showing the basal surface of a mesothelial cell (MC), the basal lamina (BL), several layers of variously oriented collagen fibrils, and part of the cytoplasm (**arrowheads**) of a greatly elongated fibroblast-like cell. **B**, section stained according to Kajikawa et al.[7] for the demonstration of elastic fibers. The elastin cores are darkly stained, particularly in the elastic fiber (**upper right**); other elastic fibers (**center** and **bottom**) contain abundant microfibrils and small elastin cores. **C**, nuclear region of elongated fibroblast-like cell in pericardial tunica fibrosa. A small elastic fiber (**arrowhead**) is shown (**lower right**). (Magnifications: **A**, ×32,000; **B**, ×43,250; **C**, ×20,300, all reduced by 27 percent.)

the luminal border, are known to constitute barriers sharply limiting the passage of macromolecules that could cross the mesothelial layer by the intercellular route. In contrast to this, the desmosomes (the other type of specialized structures present in pericardial mesothelial cells) provide points of reinforcement of intercellular adhesion but do not represent an additional permeability barrier. The number of cytoplasmic vesicles was relatively small, indicating that transport through parietal pericardial mesothelial cells by the transcellular route is limited.

Internal structural support system: The presence of large areas of overlap and interdigitation between adjacent cells would indicate that the mesothelial layer has the capacity to accommodate to changes in shape of the cells, and particularly to stretching. The bundles of filaments measuring 100 Å in diameter (intermediate filaments), in the cytoplasm of mesothelial cells are considered to constitute a cytoskeleton that serves to stabilize cell shape. These filaments are biochemically and morphologically different from the actin and myosin types of filaments.[27] Thus, the cytoplasm of mesothelial cells does have a system of internal structural support.

Function of reticulum: The functions of the Golgi complexes and the cisterns of rough-surfaced endoplasmic reticulum that were very abundant in some cells are not known. Similarly, the significance of the "clear" cells observed by us and by Kluge and Hovig[3,4] is unknown. We believe that these variations represent differences in the age of the cells. Perhaps the cells that contain more abundant endoplasmic reticulum are younger and more active, or are growing cells that are replacing senescent cells. Cells rich in endoplasmic reticulum had less abundant microvilli. An important function of the reticulum may be the elaboration of plasma membrane and filamentous components of the microvilli.

It remains to be determined whether pericardial mesothelial cells can respond to inflammation by undergoing cellular contraction and junctional separation, with a resulting increase in permeability and leakage of fluid from the interstitial spaces in the surface of the heart into the pericardial cavity. This mechanism would be analogous to that shown to occur during endothelial cell injury in inflammation.[21]

Connective Tissue Components

Pericardial basal lamina: The configuration of the pericardial basal lamina was variable. In some areas the basal lamina material was evident as a discrete layer, whereas in others it blended directly with the material surrounding the most superficial collagen fibrils in the tunica fibrosa. These findings, and the lack of hemidesmosomes or other structural devices reinforcing the attachment of the basal surfaces of the cells to the underlying connective tissue, are in accord with the observations in this study that the attachment of pericardial mesothelial cells to the submesothelial layer is very fragile. Indeed, mesothelial cells can be easily removed from unfixed specimens by contact with fingers or surgical instruments. The continuity of the basa lamina material with the interfibrillary material in th collagen layer was also demonstrated in the scannin electron micrographs of denuded areas of parietal per icardium. In these areas, the surface layer appeare smooth, and collagen fibrils were evident as discret units only when the surface layer was traumatized to th extent of removing the basal lamina material.

Collagen fibrils in fibrosa: The layers of collage fibrils in the fibrosa varied in orientation, thus allowin some degree of multidirectional stretch to take place Stretch also appeared to be permitted by the wavy ar rangement of collagen fibrils within a given bundle o layer, so that mild tension could lead to elongatio mediated by straightening of the wavy fibrils. Never theless, it would appear that very little stretch is pos sible after the collagen has been straightened out, be cause collagen fibrils are known to be very inextensi ble.[28,29] This feature seems to be the reason that smal increments in the amount of pericardial fluid at firs cause little or no increase in intrapericardial pressure and then a small additional amount of fluid can lead t a large increase in intrapericardial pressure.[26]

Relation of age to pericardial structure: Althougl the number of patients in our study was too limited t permit investigation of the ultrastructural aspects o this problem, a relation between age and connectiv tissue morphology has been observed in previous his tologic studies of human pericardium. In a study of 20 human pericardia, Hort and Bräun[30] demonstrate that: (1) pericardial collagen fibrils in younger fetuse are delicate and nonwavy; (2) in pericardium from olde fetuses, collagen fibrils become wavy as elastic fiber first develop; (3) the waviness of pericardial collage becomes maximal in young adulthood and decrease thereafter; and (4) as collagen becomes less wavy i older persons, elastic fibers do not decrease in numbe but the structure of pericardial connective tissue be comes progressively less organized. This study, and the work of Wallraff[31] showing that strips of pericardium from young subjects were more extensible than those from older subjects, also suggests that the waviness o collagen is a major determinant of pericardial disten sibility.

Differences between pericardial fibrosa and fibrosa of porcine valves: The fibrosa of parietal peri cardium appeared to be less rich in proteoglycans than is the spongiosa of porcine valves,[32] which is the laye most likely to undergo calcification in glutaraldehyde treated porcine valve prostheses.[33] In this regard, the pericardial fibrosa is more comparable with the fibrosa of porcine valves,[32] in which collagen is densely packed and elastic fibers are relatively few and small. Never theless, the collagen fibrils in the fibrosa of porcine valves are mainly oriented parallel to the free edge of the cusp,[28,29] whereas in pericardium they are much more multidirectional in orientation. It is not known whether these differences will be of importance with respect to the long-term function of valve bioprostheses made of parietal pericardium. Small elastic fibers are present in pericardium, as shown by previous histologic stud-

ies[30,34–36] and by the electron microscopic observations using specific ultrastructural staining methods in this study. The surface of anterior parietal pericardium that faces the sternum is extremely rough in texture, because of the large size of the collagen bundles and because these bundles have to be transected from their sternal attachments. The roughness of this surface may be a disadvantage in terms of the use of parietal pericardium for prosthetic patches or for construction of valve leaflets, because it may predispose to the trapping of blood elements and to thrombosis in the spaces between large collagenous bundles.

In conclusion, this study demonstrates some of the relations between structure and function in pericardium. The mesothelial cells have microvilli, which act as friction-bearing surfaces and increase the surface area available for fluid transport. They also have two sets of cytoplasmic filaments, one that provides structural support and one that mediates changes in cell shape. The junctions between adjacent cells reinforce intercellular adhesion and form a permeability barrier. The connective tissue permits only a limited amount of stretch, which is mediated by straightening of the wavy arrangement of bundles of collagen fibrils.

True Left Ventricular Aneurysm and Healed Myocardial Infarction

Clinical and Necropsy Observations Including Quantification of Degrees of Coronary Arterial Narrowing

HENRY S. CABIN, MD
WILLIAM C. ROBERTS, MD, FACC

Bethesda, Maryland

Clinical and necropsy observations are described in 28 patients (24 men) aged 31 to 85 years (mean 62) with healed myocardial infarction and a true left ventricular aneurysm. In contrast to findings in other subsets of necropsy patients with fatal coronary heart disease, chronic congestive heart failure was frequent (22 patients); angina pectoris was infrequent (4 patients) and, when present, never severe; recurrence of acute myocardial infarction (2 patients), sudden death (2 patients) and clinically evident systemic emboli (1 patient) were infrequent; survival for more than 5 years after healing of the acute infarction was infrequent (in 3 of 21 patients with clinically diagnosed acute myocardial infarcts); and survival for longer than 1 year after aneurysmectomy was lacking (0 of 7 patients). Additionally, 23 of the 28 patients had a large heart (greater than 400 g [mean 523], 26 had dilated nonaneurysmal portions of the left ventricle, and all but 1 had a large (greater than 30 percent of the left ventricular wall) myocardial infarct. In 25 of the 28 patients, two or more of the four major epicardial coronary arteries were greater than 75 percent narrowed in cross-sectional area by atherosclerotic plaques. In 992 segments (each 5 mm long) of a major coronary artery examined in 22 patients (45 segments/patient), narrowing was greater than 75 percent in 323 segments (33 percent) and ranged from 51 to 75 percent in 419 (42 percent), from 26 to 50 percent in 210 (21 percent) and from 0 to 25 percent in 40 (4 percent). Thus, the scarred, hypertrophied and aneurysmally dilated left ventricle infrequently produces chest pain or fatal arrhythmia despite diffuse, severe coronary narrowing.

Although ventricular aneurysm is a relatively frequent consequence of acute myocardial infarction, surprisingly few clinicopathologic studies are available that include more than five patients with left ventricular aneurysm and healed myocardial infarction[1–5] (Table I). Consequently, we analyzed clinical and morphologic findings in 28 necropsy patients with healed myocardial infarction and left ventricular aneurysm (Table II), focusing on the amounts of coronary narrowing present, because precise anatomic information in this area is lacking. Also, we call attention to certain clinical features in these patients that distinguish them from other subsets of patients with coronary heart disease.

Methods

Study patients: *All 28 patients fulfilled the following criteria:* (1) presence of a left ventricular free wall (endocardium, myocardium and epicardium) convex protrusion, the wall of which consisted of dense fibrous tissue with or without an occasional "island" of myocardial fibers; (2) absence of myocardial necrosis within the wall of the left ventricular aneurysm; (3) diameter of the mouth of the left ventricular aneurysm larger than or similar to that of the aneurysm itself; (4) absence of associated noncoronary heart disease; and (5) examination of all hearts by both authors.

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received February 19, 1980; revised manuscript received April 24, 1980, accepted April 29, 1980.

[a] ". . .defects in the ventricular wall which demonstrate a definite bulge in the external contour of the heart, together with a thinning of the affected region"; [b] ". . .a localized outpouching of the cavity of a cardiac chamber, with or without outward bulging of the external surface"; [c] ". . . a protrusion of a localized portion of the external aspect of the ventricle accompanied by a corresponding protrusion of the ventricular cavity"; [d] Study included 40 patients with necropsies in 27. Data refers to all 40 patients unless specified. [e] minimal number; [f] heart weight >100 g above expected normal.

CHF = congestive heart failure; LV = left ventricular; MI = myocardial infarct; Pts = patients; – = no information.

The 28 patients (Table II) ranged in age from 31 to 85 years (mean 62); 13 were aged 65 years or older, and 24 were men. Chronic congestive heart failure occurred in 22 patients (79 percent), angina pectoris in 4 (14 percent) and clinical episodes compatible with systemic emboli in 1 (4 percent). A history of systemic hypertension, before the acute myocardial infarction, was present in 13 patients, and 5 had diabetes mellitus. Clear documentation of acute myocardial infarction was present in 21 patients and only 3 of them survived for as long as 5 years (Fig. 1). Aneurysmectomy (with coronary bypass in three patients) was performed in seven patients: in six for chronic congestive heart failure and in one for refractory arrhythmias; none of the seven was alive 1 year after operation.

Acute myocardial infarction recurred in two patients and was fatal in one. Thirteen patients died of refractory congestive heart failure; two died suddenly; six from noncardiac causes and one from rupture of the left ventricular aneurysm. In the latter patient a septic process involved the aneurysmal wall. Five of the seven patients undergoing aneurysmectomy died as a direct consequence of the operation, and the other two, from persistent chronic congestive heart failure.

The aneurysm was diagnosed clinically in 12 patients (43 percent): in 6 patients (21 percent), the electrocardiogram was consistent with aneurysm and in 3 (11 percent) the chest radiograph suggested aneurysm; the aneurysm was diagnosed with angiography in each of the 10 patients in whom this procedure was performed.

Examination of coronary arteries: The four major coronary arteries were examined in all 28 patients. In addition, in 22 patients in whom the entire lengths of the right, left main, left anterior descending and left circumflex coronary arteries were available, each of these four arteries was cut transversely into 5 mm long segments and each segment was labeled, processed for histologic study, and a histologic section stained by the Movat method[6] was prepared and examined.

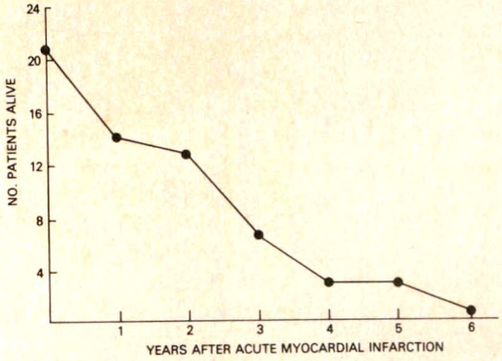

FIGURE 1. Length of survival after acute myocardial infarction in 21 necropsy patients with left ventricular aneurysm and unequivocal history of acute myocardial infarction.

[a] Clinically silent acute myocardial infarction; [b] heart weight does not include operatively excised specimen.
AMI = acute myocardial infarct; AP = angina pectoris; CA = coronary arteries; CHF = congestive heart failure; DM = diabetes mellitus; LV

The degree of narrowing in all 5 mm long segments was determined by examination of the histologic sections magnified 25 to 50 times. *The percent of cross-sectional area narrowing* by atherosclerotic plaque was divided into four categories of narrowing: 0 to 25, 26 to 50, 51 to 75 and 76 to 100. The accuracy of these determinations was verified by random evaluations by other observers and by videoplanimetry, and both the intra- and interobserver error was less than 5 percent.[7]

Results

The ventricular aneurysm: The hearts in the 28 patients (Table II) weighed from 330 to 705 g (mean 523) and in 23 patients the weight was over 400 g. In 20 patients the aneurysm involved the *anterior* (11 patients) (Fig. 2), *posterior* (6 patients) (Fig. 2) or *lateral* (3 patients) (Fig. 3 and 4) walls of the *mid or basal third,* or both, of the left ventricle, with or without involvement of the apical third. In the other eight patients, the aneurysm was designated as *apical* because it involved mainly or only the apical third of the left ventricle, involving in each the entire wall in this portion of the heart (Fig. 5 and 6).

The coronary arteries: Among the 28 study patients (Table II), a total of 112 major (right, left main, left anterior descending and left circumflex) epicardial coronary arteries were examined. At least one of the four major epicardial coronary arteries was narrowed greater than 75 percent in cross-sectional area by atherosclerotic plaques in all 28 patients (Table III). Of the 112 major coronary arteries in the 28 patients, 71 (63 percent) were greater than 75 percent narrowed in cross-sectional area by atherosclerotic plaques, an average of 2.5 of 4.0 coronary arteries/patient. The left main coronary artery was narrowed greater than 75 percent in cross-sectional area in two patients.

Analysis of the 992 five mm long coronary arterial segments in 22 patients disclosed atherosclerotic narrowing of cross-sectional area of 76 to 100 percent in 323 segments (33 percent) 7 of 51 to 75 percent in 419 (42 percent), of 26 to 50 percent in 210 (21 percent) and of 0 to 25 percent in 40 (4 percent) (Table IV). The left anterior descending coronary artery was significantly ($p < 0.05$) more severely narrowed than the other three

= left ventricular; mo = months; Op = operation; SAP = systolic arterial pressure; SCD = sudden coronary death; SE = systemic embolus; SH = systemic hypertension; Th = thrombus; XSA = cross-sectional area; + = present or positive; 0 = absent or negative; – = no information available.

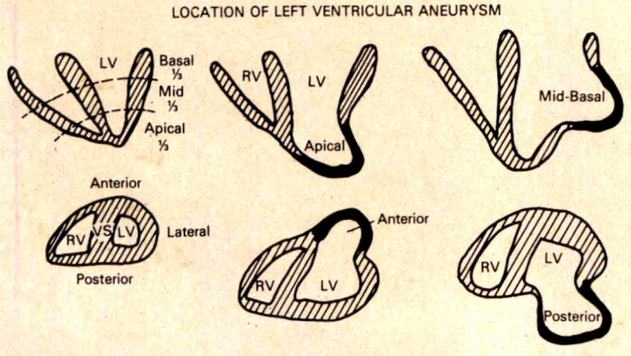

FIGURE 2. Locations of left ventricular aneurysms. The locations of apical (**top middle**) and mid-basal (**top right**) aneurysms are shown. The anterior, lateral and posterior walls of a transverse cardiac ventricular slice (**bottom left**) and the locations of anterior (**bottom middle**) and posterior (**bottom right**) wall aneurysms are shown. An aneurysm is considered anterior, posterior or lateral if it involves the anterior, posterior or lateral walls of the mid or basal third, or both, of the left ventricle with or without involvement of the apical third. An aneurysm is considered apical if it is limited to the apical third of the left ventricle. LV = left ventricle; RV = right ventricle; VS = ventricular septum.

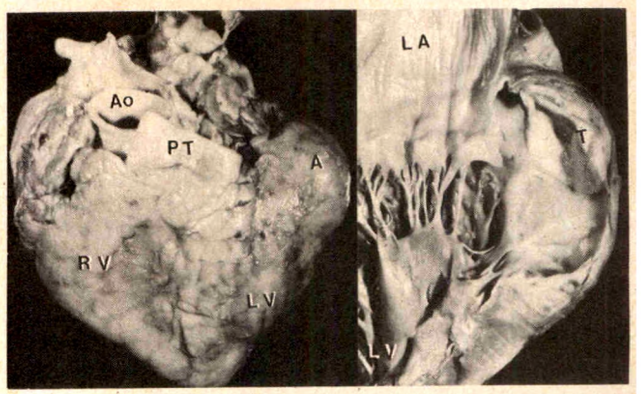

FIGURE 3. Patient 19 (Table II). Exterior view (**left**) and longitudinal section (**right**) of the heart from an 80 year old man (GT 72A-233) without a history of acute myocardial infarction but with angina pectoris and congestive heart failure. He died from carcinoma of the bladder. A lateral wall left ventricular aneurysm (A) that contains thrombus (T) is present. Ao = aorta; LA = left atrium; LV = left ventricle; PT = pulmonary trunk; RV = right ventricle.

major coronary arteries (Fig. 7). The mean percent of 5 mm segments severely narrowed in the proximal half of the right, left anterior descending and left circumflex coronary arteries was similar to that in the distal half of each of these arteries (Fig. 8).

Of the 22 patients in whom the amount of coronary arterial narrowing was quantified, 10 had an anterior, 6 an apical, 4 a posterior and 2 a lateral left ventricular aneurysm. In the 10 patients with an *anterior* left ventricular aneurysm, 79 (60 percent) of 132 five mm segments of the left anterior descending, 61 (34 percent) of 179 segments of the right and 19 (17 percent) of 115 segments of the left circumflex coronary artery were narrowed greater than 75 percent in cross-sectional area. In the 6 patients with an *apical* aneurysm, 35 (50 percent) of 70 segments of the left anterior descending, 17 (13 percent) of 130 segments of the right and 12 (20 percent) of 61 segments of the left circumflex coronary artery were narrowed greater than 75 percent. In the four patients with a *posterior* aneurysm, 26 (37 percent) of 71 segments of the left anterior descending, 40 (5(percent) of 80 segments of the right and 24 (50 percent of 48 segments of the left circumflex coronary artery were narrowed greater than 75 percent. In the two patients with a *lateral* aneurysm, 1 (4 percent) of 26 segments of the left anterior descending, 1 (3 percent) o 34 segments of the right and 6 (55 percent) of 11 segments of the left circumflex coronary artery were narrowed greater than 75 percent.

Comments

Clinical versus anatomic definition of ventricular aneurysm: Our study included only patients with a localized convex protrusion of the entire thickness of the left ventricular wall at necropsy. The wall of the aneurysm formerly was the wall of left ventricle, and the mouth of the aneurysm was larger than or as large as the maximal diameter of the aneurysm. These patients therefore had a *true anatomic* left ventricular aneurysm. When a localized left ventricular protrusion is

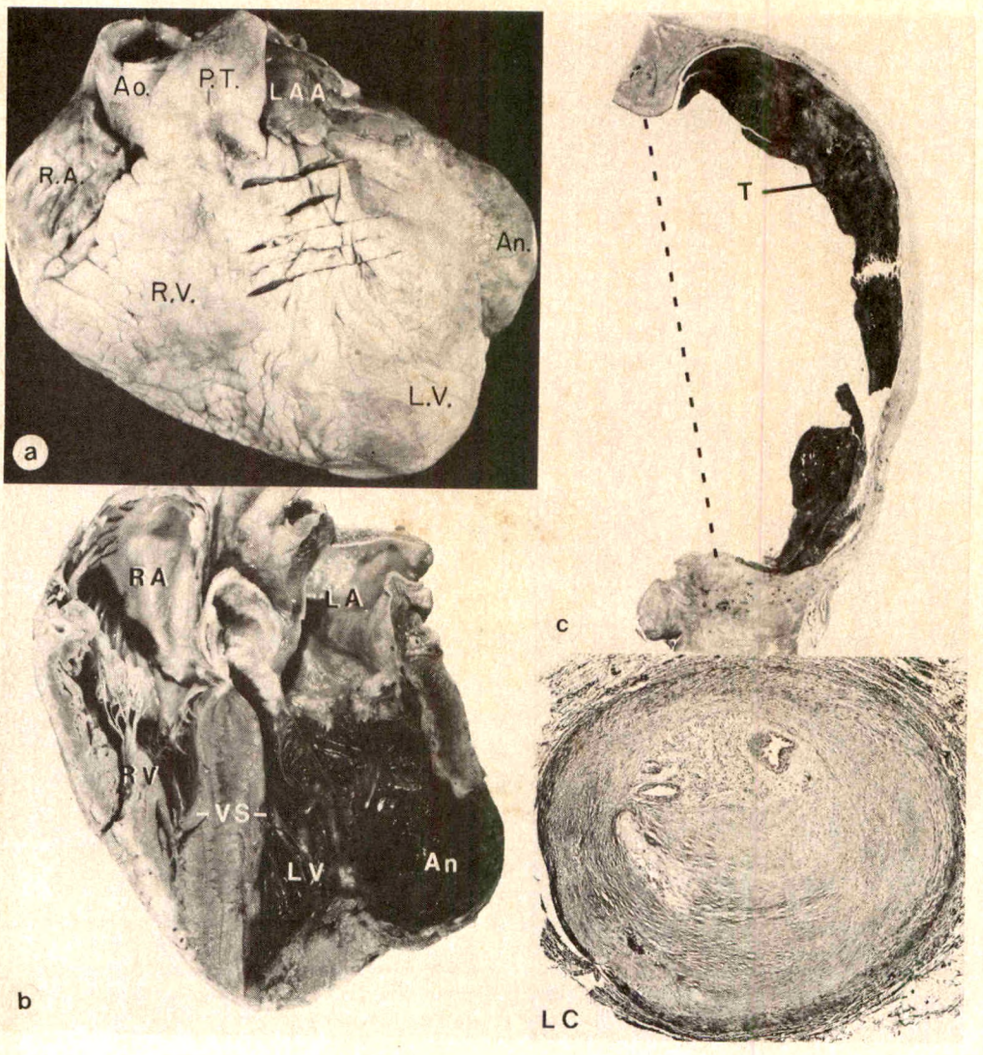

FIGURE 4. Patient 11 (Table II). Exterior view (**a**) and longitudinal section (**b**) of the heart and photomicrograph of the aneurysmal wall (**c**) and of the left circumflex (LC) coronary artery at point of maximal narrowing from a 65 year old man (A67–71) with no history of acute myocardial infarction or angina pectoris who died of progressive congestive heart failure. **a**, exterior view of the anterior surface of the heart showing the lateral wall left ventricular (L.V.) aneurysm (An.). **b**, longitudinal section of the heart showing the lateral wall left ventricular aneurysm and the dilated nonaneurysmal portion of the left ventricular cavity. VS = ventricular septum. **c**, histologic section of the scarred aneurysmal wall, the thrombus (T) adherent to its wall, and the mouth of the aneurysm (**dashed line**) (Movat stain ×2, reduced by 25 percent). ×2 **LC,** left circumflex coronary artery at its point of maximal narrowing. (Hematoxylin-eosin ×26, reduced by 25 percent. present at necropsy, the protrusion must have been present during life in both ventricular systole and diastole. Patients in whom a localized protrusion is observed only during ventricular systole (*functional* aneurysm) would not have a protrusion at necropsy, and therefore such patients are not included in this analysis. Because the wall of the left ventricular aneurysm in our patients contained few if any myocardial fibers, the anatomic aneurysm could have been either akinetic or dyskinetic during life but not hypokinetic. Thus, clinical studies that have defined left ventricular aneurysm by hypokinetic wall motion abnormality or by akinetic or dyskinetic portions of wall,[8–16] without specifying protrusion during both phases of the cardiac cycle,[17–19] have included many patients without an anatomic aneurysm.

A precise definition of left ventricular aneurysm is crucial, in our view, because the findings to a large extent are dependent on the definition of aneurysm. In contrast to previous necropsy studies of patients with left ventricular aneurysm,[1–5,20] in our study all our patients had an aneurysm at the site of *healed* myocardial infarction and patients with an aneurysm at the sites of acute infarction were excluded. Additionally, our study excluded patients with associated noncoronary types of heart disease. Furthermore, in contrast to previous studies,[2,3,5] our study is based on personal examination of all the hearts of the patients included, rather than on examination of autopsy protocols, a recognized relatively inaccurate method of obtaining cardiovascular information.[21]

Pathologic Features

Characteristics of the aneurysm: In 27 of our 28 patients, the *left ventricular scars* involved more than 30 percent of the left ventricular wall. In none of five previously reported necropsy studies in English involving more than 20 patients[1–5] (Table I) was the size of the myocardial infarcts (which healed) quantified. However, in the study by Schlichter et al.,[2] the infarcts

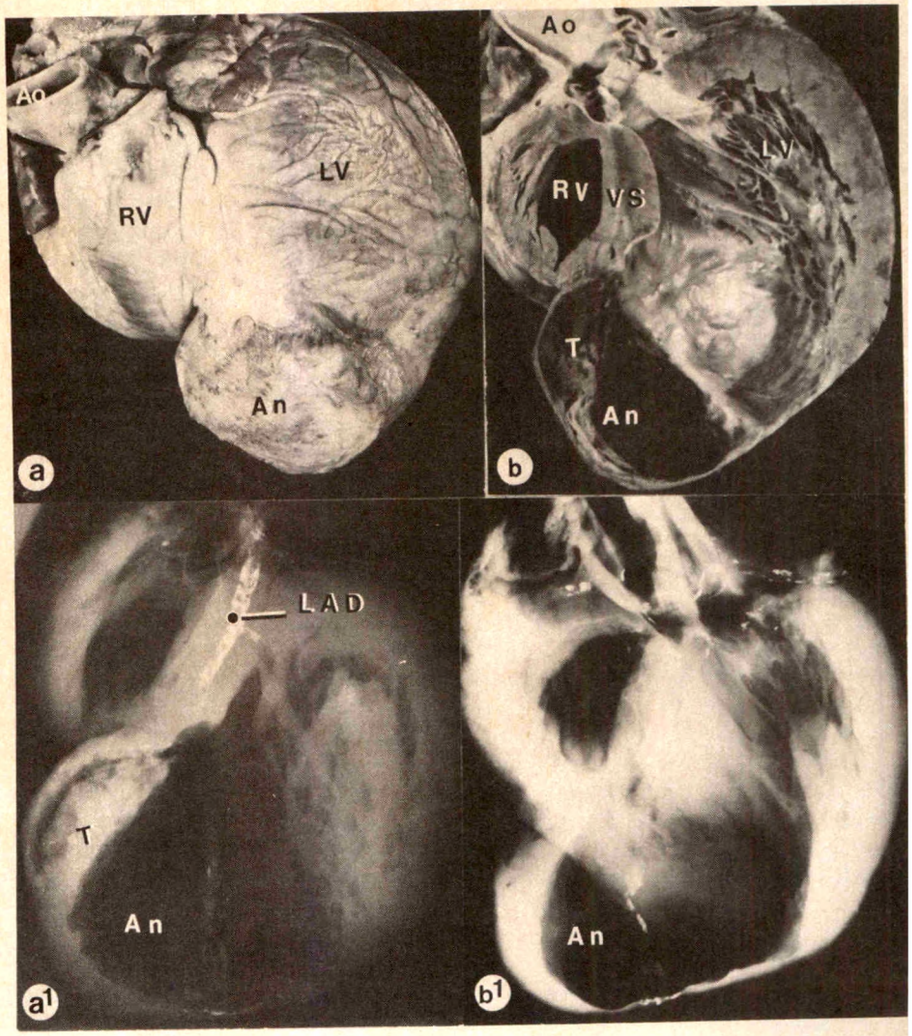

FIGURE 5. Patient 18 (Table II). Unopened heart and roentgenogram (**a** and **a**[1]) and after a longitudinal cut (**b**, **b**[1]) from a 78 year old man (GT 76A-171) who died of congestive heart failure 5 years after an acute myocardial infarction. **a**, exterior view of the heart showing a large apical wall left ventricular (LV) aneurysm (An). **a**[1], roentgenogram of **a** showing calcific deposits in the left anterior descending (LAD) coronary artery and in the wall of the aneurysm. The intraaneurysmal thrombus (T) also is seen. **b**, longitudinal section of the heart showing the apical aneurysm and the markedly dilated nonaneurysmal portion of the left ventricular cavity. **b**[1], roentgenogram of **b** showing calcific deposits in the coronary arteries and in the wall of the aneurysm. Ao = aorta; RV = right ventricle; VS = ventricular septum.

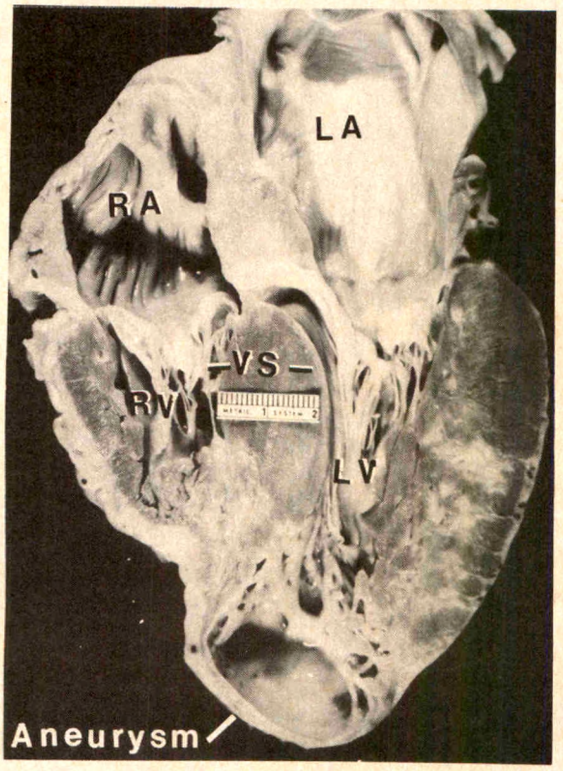

FIGURE 6. Patient 20 (Table II). Longitudinal section of the heart from an 80 year old man (GT 72A-219) who had no clinical evidence of coronary heart disease and died of acute pneumonia. An apical left ventricular (LV) aneurysm is present. The nonaneurysmal wall is hypertrophied and the left ventricular cavity is not dilated. LA = left atrium; RA = right atrium; RV = right ventricle; VS = ventricular septum.

were described as "large," apparently in most patients.

Scarring in portions of the left ventricular wall not involved in or adjacent to the aneurysm was absent in our 28 patients. This finding was not reported in previous studies[1–5,20,22–24] of necropsy patients with left ventricular aneurysm. The significance of this observation is that the aneurysm represents, with few exceptions, the only myocardial infarction that occurred.

The nonaneurysmal portion of the left ventricular wall was hypertrophied in 24 (86 percent) of our 28 patients and the *heart weight was increased* (greater than 350 g in women and greater than 400 g in men). In 20 of the 24 patients, the heart weighed 500 g or more. Only two of five previous necropsy studies (Table I) mentioned heart weight. Phares et al.[1] found the heart weight to be "100 grams or more above the predicted normal" in 33 (83 percent) of 40 patients and Dubnow et al.,[4] found it "100 grams or more above expected normal" in 66 (83 percent) of their 80 patients.

The portion of left ventricular cavity uninvolved by aneurysm was dilated in 26 (93 percent) of our 28 patients. Information on left ventricular cavity size is lacking in previous necropsy studies of patients with left ventricular aneurysm[1–5,20,22–24] (Table I).

* 75 percent or greater narrowing of cross-sectional area.

Characteristics of the coronary arteries: *Th degree of narrowing of the epicardial coronary arterie* in necropsy patients with healed left ventricular aneurysm was recognized as "severe" in previous studie (Table I)[1,2,4,5] as well as in our patients. Phares et al. mentioned "severe" narrowing of the left anterior descending coronary artery in a "majority" of their 4(patients. Schlichter et al.[2] described "severe" coronary narrowing in an unspecified number of their 102 patients. Dubnow et al.[4] described "occlusive lesions" in one or more coronary arteries in all of their 80 patients and Davis and Ebert[5] reported greater than 50 percent luminal narrowing (whether cross-sectional area or diameter reduction not specified) in two or more of the three major (left anterior descending, left circumflex and right) coronary arteries in 20 of their 24 necropsy patients. In 25 of our 28 patients, two or three of the three major coronary arteries were narrowed greater than 75 percent in cross-sectional area by atherosclerotic plaques, and in the other 3 patients, only one artery was similarly narrowed.

Although several previous studies have superficially mentioned degrees of coronary narrowing in necropsy patients with left ventricular aneurysm, *quantitative information on the extent and distribution of the narrowing in each of the four major coronary arteries* has not been reported previously. In 22 of our 28 patients, an average of 33 percent (range 3 to 61) of the lengths of the four major arteries were narrowed 76 to 100 percent and another 42 percent were narrowed 51 to 75 percent in cross-sectional area by atherosclerotic plaque. The left anterior descending artery had significantly more 5 mm long segments narrowed severely (greater than 75 percent) than did the other major arteries. This was true for the patients with an anterior wall or apical aneurysm (16 patients) but not in the patients with a posterior or lateral wall aneurysm (6 patients).

Clinical Features

Sex and age: It is well recognized that coronary heart disease is more frequent in men than in women by a ratio of about 2:1. Among necropsy patients with left

* Data based on 22 patients.

ventricular aneurysm, this sex difference is more pronounced. Of our 28 patients, 24 were men and 4 were women (Table II), yielding a man to woman ratio of 6:1. Of the 287 necropsy patients with left ventricular aneurysm reported on in four previous studies[1–4] (Table I), 224 (78 percent) were men and 63 (22 percent) were women. Of necropsy patients with fatal coronary heart disease, those with compared to those without left ventricular aneurysm tend to be older. The mean age of 185 necropsy patients with left ventricular aneurysm from three previously reported studies[1,3,4] was 69 years. The mean age of our 28 patients was 62 years (range 31 to 85), and 17 (61 percent) were 60 years of age or older (Table II).

Heart failure and angina: *Chronic congestive heart failure* was the most frequent manifestation of cardiac dysfunction in our patients, occurring in 22 (79 percent) of the 28. In contrast, angina pectoris was present in only 4 (14 percent) of the 28 patients and in each of them it was infrequent (Table II). Other investigators have also noted a high frequency of chronic congestive heart failure in their patients: in 24 (60 percent) of 40 patients[1]; in 71 (71 percent) of 102 patients[2]; in at least 61 (75 percent) of 80 patients[4]; and in 35 (88 percent) of 40 patients[5] (Table I). The frequency of angina pectoris in necropsy patients with left ventricular aneurysm has rarely been mentioned. Davis and Ebert[5] recorded angina in 25 (63 percent) of their 40 patients reported

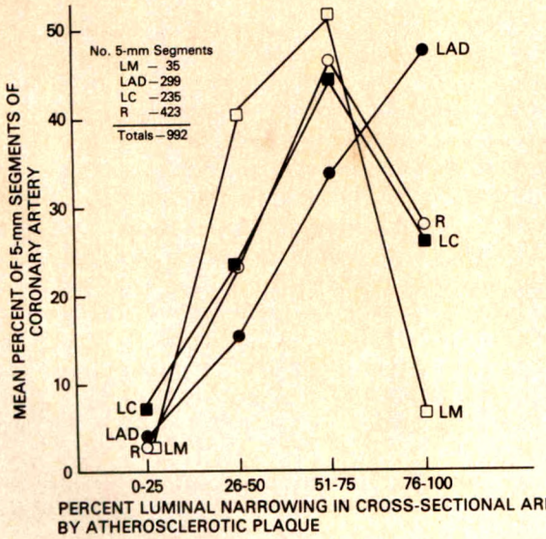

FIGURE 7. Mean percent of 5 mm long segments of the left main (LM), left anterior descending (LAD), left circumflex (LC), and right (R) coronary arteries narrowed to various degrees in 22 study patients with healed myocardial infarction and left ventricular aneurysm.

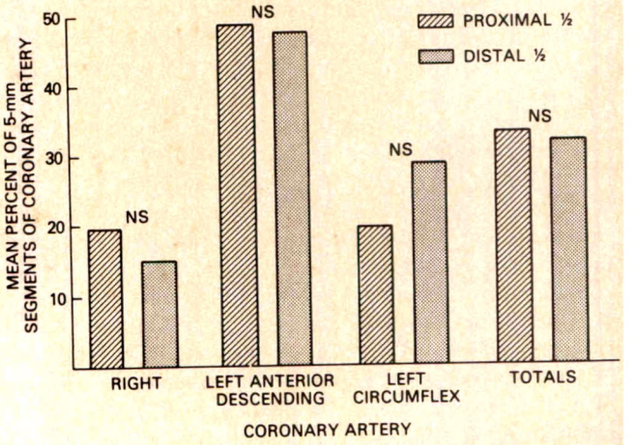

FIGURE 8. Mean percent of 5 mm long segments of the right, left anterior descending and left circumflex coronary arteries narrowed more than 75 percent in cross-sectional area by atherosclerotic plaques in the proximal and distal halves of each artery in 22 study patients with healed myocardial infarction and left ventricular aneurysm. NS = no significant difference.

to have left ventricular aneurysm, but the criteria for diagnosis of aneurysm in their patients were imprecise. Phares et al.[1] found severe angina in 5 (13 percent) of their 40 patients. All our patients with chronic congestive heart failure had dilated nonaneurysmal portions of left ventricle, in general a fairly reliable anatomic indicator for the presence of chronic congestive heart failure in patients without valvular heart disease or intercirculatory shunts. It appears that the dilated left ventricle even in patients with severely narrowed coronary arteries infrequently causes angina pectoris, and when it does, the angina is mild and infrequent.

Systemic hypertension: This was present in at least 13 of our 28 patients before the acute myocardial infarction and in the remaining 15 patients information regarding the level of the systemic blood pressure before the infarction was inadequate. Only four patients had systemic hypertension after healing of the acute infarction (Table II). Thus, systemic hypertension is infrequent in patients with healed myocardial infarction and true left ventricular aneurysm. It seems likely that the explanation for the considerable cardiomegaly in most of our patients was the presence of systemic hypertension, undiagnosed in most, before the acute myocardial infarction. Also, it is likely that the poorly contracting aneurysmally dilated left ventricle after healing of the acute infarction was incapable of creating sufficient cardiac output to allow elevation of the systemic arterial pressures. The frequency of systemic hypertension in previously described necropsy patients with left ventricular aneurysm has ranged from 22 percent (14 of 65 patients)[3] to 68 percent (69 of 102 patients).[2] It is not apparent from these previous studies[1–4] (Table I) whether the systemic hypertension was present before or after the acute myocardial infarction, or both, or whether the information was derived by history or by actual blood pressure recording.

Thromboembolism: Although left ventricular aneurysms frequently contain thrombi, the frequency of *clinical events compatible with systemic emboli* is quite variable. Of our 28 patients, 11 (39 percent) had intraaneurysmal thrombi but only 1 had an event compatible with a systemic embolus; none of the 17 patients without intraaneurysmal thrombi had a compatible event (Table II). Of 102 patients with left ventricular aneurysm reported by Schlichter et al.,[2] 55 (54 percent had intraaneurysmal thrombi; and at least 36 (35 percent) of their 102 patients had a clinical event compatible with a systemic embolus. Of the 80 patients reported on by Dubnow et al.,[4] 52 (65%) had intraaneurysmal thrombi, and 10 (minimum) had a clinical embolic event. Only 9 (14 percent) of the 65 patients described by Abrams et al.[3] had intraaneurysmal thrombi, and the frequency of clinical systemic emboli was not mentioned (Table I). Despite the variability in the reported frequency of clinical events compatible with systemic emboli in patients with left ventricular aneurysm and healed myocardial infarction, intraaneurysmal thrombus formation is frequent and it would, therefore, appear reasonable to use anticoagulant agents in thes patients.

Clinical diagnosis: Surprisingly, clinical diagnosi of left ventricular aneurysm by means other than lef ventricular angiography is infrequent. The diagnosis o left ventricular aneurysm was made in each of our 1(patients who underwent left ventricular angiograph; but among the other 18 patients, diagnosis by ches radiograph or electrocardiogram was made in only 2 Persistent S-T elevation in the electrocardiogram afte healing of the acute myocardial infarction was observe in only 6 (21 percent) (4 of whom also had angiography of our 28 patients. In previous studies clinical diagnosi of left ventricular aneurysm was made in only 4 (6 per cent) of 65 necropsy patients,[3] in 13 (16 percent) of 8(necropsy patients,[4] and in 6 (22 percent) of 27 necropsy patients[5] (Table I).

Prognosis: *Survival* in patients who manifest a lef ventricular aneurysm after a clinically documente acute myocardial infarction is clearly diminishe compared with that in patients with healed myocardia infarction unassociated with aneurysm. Of our 21 pa tients whose acute infarction was diagnosed clinically only 3 lived 60 months or longer thereafter (Fig. 1). Ir previous studies of patients with left ventricular aneu rysm and earlier clinical documentation of acute myo cardial infarction, only 8 (12 percent) of 66[2] and 13 (27 percent) of 48[4] survived 5 years or longer after infarctior (Table I).

Causes of death: It is well recognized that most pa tients with severe coronary arterial narrowing from atherosclerosis either die suddenly, from so-called sudden coronary death or from acute myocardial infarction. This situation holds whether the coronary event is a first or a subsequent one. Such, however, was not the situation among our patients with left ventricular aneurysm and healed myocardial infarction (Table II). Only 2 of our 28 patients died suddenly, and only 1 had a fatal acute myocardial infarction. Thirteen of our 28 patients died from intractable congestive heart failure and 5 from consequences of left ventricular aneurysmectomy. It is likely that congestive heart failure would have proved fatal in at least four of these latter five patients. Rupture of a healed true left ventricular aneurysm is an extremely rare occurrence. Rupture did occur, however, in one of our patients but only because septicemia developed and a septic process invaded the aneurysmal wall. Chronic congestive heart failure was not as frequent a fatal event, and fatal acute myocardial infarction was more frequent in previous necropsy studies[1,3–5] (Table I). "Sudden coronary death" was noted to be an infrequent mode of death in previous reports (6 [15 percent] of 40 patients,[1] none of 102 patients,[2] none of 65 patients[3] and none of 24 patients).[5]

Conclusions: Thus, from our study of 28 necropsy patients with true anatomic left ventricular aneurysm and healed myocardial infarction, the following conclusions appear justified: The myocardial infarct is large; the heart weight is increased and the nonscarred

left ventricular wall is hypertrophied; the nonaneurysmal portions of the left ventricular cavities are dilated; the major epicardial coronary arteries are severely narrowed; chronic congestive heart failure is frequent and is the most common cause of death; angina pectoris is infrequent; recurrence of acute myocardial infarction is infrequent; clinical events compatible with systemic emboli are infrequent despite frequent intraaneurysmal thrombus; the long-term prognosis is poor; sudden death is infrequent; and clinical diagnosis of the left ventricular aneurysm without left ventricular angiography is infrequent.

Response to Exercise Early After Uncomplicated Acute Myocardial Infarction in Patients Receiving No Medication: Long-Term Follow-Up

GERALD M. KOPPES, MD, FACC
WILLIAM KRUYER, MD
CHARLES H. BECKMANN, MD, FACC
FREDERIC G. JONES, MD, FACC

San Antonio, Texas

Cardiovascular function and prognosis have not been adequately defined early after an uncomplicated acute myocardial infarction in patients given no medication. Ninety such patients were studied with treadmill testing submaximally at 3 weeks and maximally at 8 weeks after infarction. The exercise heart rate, rate-pressure product and oxygen uptake were, respectively, 120 ± 17 beats/min, 179 ± 43 and 17.4 ± 1.0 ml/kg per min at 3 weeks and 157 ± 20, 271 ± 55 and 24.3 ± 3.7 at 8 weeks. Exercise variables at submaximal equivalent exercise work did not change from 3 to 8 weeks. At maximal exercise 15.6 percent of patients had S-T changes alone, 8.9 percent had angina alone and 12.2 percent had both. Patients were followed up for a mean of 23.7 months for complications—death, reinfarction, bypass grafting and progression to functional class III and IV. Complications occurred in 27 percent of patients with both angina and S-T changes, 29 percent of those with S-T changes alone, 25 percent of those with angina alone, 8 percent of those with ventricular arrhythmia alone, 12 percent of those with a normal 8 week treadmill test and in 17 percent of the group as a whole. Another 18 patients who were given no medication and whose course was uncomplicated could not perform a maximal 8 week treadmill test because of angina pectoris or S-T segment depression, or both, and 56 percent of these had long-term complications.

In conclusion, these reference values serve as safe limits in performing treadmill testing early after acute myocardial infarction. S-T changes or angina, or both, and inability to complete a maximal 8 week treadmill test identify patients at risk for later complications even though these patients may have been considered to be in a low risk category clinically.

Cardiovascular function has not been completely defined in the early period after an acute myocardial infarction. Until recently, exercise testing has been used primarily to study patients suspected of having clinical or subclinical coronary artery disease. Exercise tests in the early period after acute myocardial infarction are now being performed and the data obtained frequently reported.[1–13] Reliable baseline responses to assess abnormal values have not been published and long-term follow-up results have not been described. A reliable reference group of patients studied after acute myocardial infarction is needed as a standard for comparison before exercise treadmill testing is used in this early period for diagnostic purposes. Safe limits must be determined.

In this paper we define exercise variables in patients who had an uncomplicated acute myocardial infarction and who underwent treadmill exercise testing submaximally at 3 weeks and maximally at 8 weeks after infarction. We propose to assess the exercise capacity of these patients after an acute myocardial infarction as has been done for normal subjects and patients with chronic coronary artery disease[14,15] and to correlate these data with long-term follow-up.

Methods

Study patients: One hundred eight patients, 93 men and 15 women, were studied. Their average age was 53 ± 10 years (range 30 to 79). All patients had an uncomplicated acute myocardial infarction; that is, none had congestive heart failure or angina pectoris during rehabilitation.

The diagnosis of an acute transmural myocardial infarction was substantiated by all of the following: chest pain typical of coronary artery disease, serial acute serum enzyme changes and evolving Q wave abnormality with acute S-T and T wave changes in the electrocardiogram. The diagnosis of subendocardial myocardial infarction was substantiated with chest pain typical of coronary artery disease, serial diagnostic enzyme changes, and acute S-T and T wave changes persisting for more than 48 hours. No patient had a history of angina pectoris during rehabilitation after myocardial infarction. Three patients had mild cardiomegaly on chest X-ray examination, as defined by a cardiothoracic ratio greater than 50 percent, but none had clinical evidence of congestive heart failure. No patient was taking digitalis, propranolol or any antiarrhythmic agent. No history of syncope or other cardiac disease was elicited. No patient had undergone previous coronary bypass surgery. Mitral valve prolapse and valvular heart disease were absent.

Classified functionally according to New York Heart Association[16] *criteria at the 8th week after acute myocardial infarction,* 59 were in class I, 49 in class II, and none in class III or IV. No patient had been under treatment for ventricular arrhythmia, angina pectoris or congestive heart failure. The site of the recent myocardial infarction was anterior in 30, inferior or posterior, or both, in 52 and subendocardial in 26 patients.

The study group was derived from 410 patients who entered Wilford Hall U. S. Air Force Medical Center between October 1975 and March 1978 with a transmural or subendocardial acute myocardial infarction. Other patients with uncomplicated myocardial infarction were not studied because they were taking cardiotropic medications. The patients were studied with exercise stress testing at 3 and 8 weeks after infarction. Progressive rehabilitation with passive and active range of motion exercises was started in the coronary care unit. After discharge from the unit, the patients were gradually allowed to walk and, by the 3rd week, they were walking 1 mile daily without cardiovascular symptoms.

Treadmill testing: The procedure was performed in the fasting subjects in the morning, and it was usually their first experience with treadmill walking. They were not allowed to support their weight on the handrails. Subjects with any of the following findings were excluded from our "standard" study: (1) any physical ailment that could limit treadmill performance; (2) a submaximal treadmill effort, as judged by those monitoring the treadmill test; (3) an electrocardiogram at rest showing a bundle branch block pattern; and (4) blood pressure at rest greater than 140/90 mm Hg. The study purpose and details were explained, and informed consent was obtained from each patient according to the Wilford Hall Medical Center Human Experimentation Committee.

Exercise protocol: An electrocardiogram during exercise was continuously monitored using a Mason-Likar 12 lead system.[17] The exercise test at the 3rd week after myocardial infarction consisted of three minute stages at 1.7 miles/hour with grades of 0, 5 and 10 percent, respectively. At the 8th week after infarction, the patients underwent a maximal Bruce treadmill test[18] after going through the initial stages of the 3rd week protocol. No complications were encountered. The exercise tests at 8 weeks were maximal; that is, they were symptom-limited or limited by the development of progressive angina pectoris, S-T segment depression greater than 4 mm S-T or a decrease in systolic blood pressure of more than 10 mm Hg. Electrocardiographic recordings were made before exercise in the lying and standing positions, during the last 30 seconds of each level of exercise, during the immediate postexercise period, and every 3 minutes thereafter until ventricular ectopic status or S-T segment changes had returned to control level. Blood pressure cuff recordings were obtained at 1 to 3 minutes intervals throughout the exercise period.

Ninety of the 108 patients with uncomplicated myocardial infarctions were able to exercise for the total 9 minutes of our 3 week treadmill testing protocol and maximally at 8 weeks. These 90 patients are the source of our baseline standard of exercise responses for patients after myocardial infarction. The 18 patients unable to exercise maximally at 8 weeks were limited by angina alone (8 patients), both angina and S-T segment depression (8 patients) or S-T depression alone (2 patients). The condition of all these patients had been considered clinically uncomplicated.

For statistical analysis, we used the unpaired *t* test. Subgroup sample sizes were too small for chi-square analysis.

Results

Exercise Test Results

S-T depression and angina: None of the 90 study patients were limited by angina pectoris at the 3rd or 8th week of exercise. In all, fatigue, progressive shortness of breath or leg discomfort was the exercise end point. Angina pectoris developed in 9 patients (10 percent) at 3 weeks and in 19 patients (21 percent) at 8 weeks with maximal exercise. These patients who experienced angina at maximal exercise denied the presence of angina except during the exercise testing. One mm or greater S-T segment depression occurred in 3 patients (3 percent) at 3 weeks and in 25 patients (27 percent) at 8 weeks with maximal exercise. Two mm or greater S-T segment depression occurred in no patient at 3 weeks and in eight patients (9 percent) at 8 weeks. Thirteen patients had S-T elevation with exercise. All but three of these also had S-T depression. In two of these three, the S-T elevation was in leads corresponding to a prior anterior infarction.

Evidence of ischemia (presence of angina or S-T segment displacement 1 mm or greater from resting values) was seen in 13 percent of patients at 3 weeks and in 30 percent of patients at 8 weeks in the 90 reference patients. Ischemia was present in 18 (100 percent) of 18 patients not exercising maximally at 8 weeks.

Ventricular arrhythmia: Table I shows the results of ventricular arrhythmia analysis in the 90 patients. The variables assessed were the presence of any premature ventricular complexes, more than three premature ventricular complexes/min, multifocal premature ventricular complexes, bigeminy, couplets and ventricular tachycardia (three or more consecutive beats). In more than half (50) of the patients, premature ventricular complexes developed with exercise; however, these complexes were reproducible from the 3rd to the 8th week in only 16 (32 percent) of the 50. Bigeminy and couplets occurred in 13 and 11 percent of patients, respectively. The type and prevalence of premature ventricular complexes did not change significantly in

* Mean ± 1 standard deviation.

the group as a whole from the 3rd to the 8th week. Ventricular tachycardia was a rare occurrence. No sustained arrhythmia was encountered and there was no arrhythmic morbidity.

Hemodynamic responses: The hemodynamic responses to exercise as evaluated by heart rate, systolic blood pressure, rate-pressure product, estimated oxygen consumption[14] and exercise time are shown in Table II, where values are assessed as mean ± 1 standard deviation, and in Table III, where values are shown for the 10th, 50th (median) and 90th percentiles. All patients had these measurements at both the 3rd and 8th week after myocardial infarction. No patient experienced a decrease in heart rate or systolic blood pressure with exercise at any stage. There was no significant difference in the heart rate, systolic blood pressure or maximal rate-pressure product at 3 weeks between the 90 patients forming the baseline standards and the 18 patients who were unable to exercise maximally at 8 weeks. However, the 8 week values in the 18 patients were lower because ischemia limited their testing.

The heart rate and rate-pressure product at the same 9 minute exercise time (1.7 miles/h, 10 percent grade) at both the 3rd and the 8th week were compared to detect any serial change in these functions at an equivalent work load. There was no significant change in these values from the 3rd to the 8th week.

Relation to age and infarct location (Table IV): Duration of exercise at the 8th week (Bruce protocol) increased significantly with decreasing age. Maximal heart rate, oxygen consumption and rate-pressure product at the 8th week were also age-related, with decreasing values as age increased. The older the patient, the closer to a maximal value was his exercise response when the modified 3rd week treadmill protocol was used. There was not a wide individual variation within age groups of any of the variables studied. There was no relation between the estimated oxygen uptake, the maximal heart rate or rate-pressure product determination and site of infarction. Subgroups other than those related to age are not specifically identified because the population is homogeneous.

Clinical follow-up results: All 108 patients were followed up for a mean of 23.7 months. The complications assessed during the follow-up period were death, reinfarction, aortocoronary saphenous vein bypass grafting (for severe limiting angina only) or progression to clinical functional class III or IV. Death occurred in only two patients, one with S-T depression only and one with neither angina nor S-T depression on exercise. Among the 90 patients exercising maximally (not limited by cardiovascular symptoms or signs), complications occurred in 27 percent of those with both angina and S-T depression, in 29 percent of those with S-T segment depression only, in 25 percent of those with angina only, in 8 percent of those with ventricular arrhythmia only, in 12 percent of those with a normal exercise response and in 17 percent of the group as a

whole. The occurrence of long-term complications in patients with an ischemic 8 week test response was significantly greater than that in patients with a nonischemic response ($p < 0.05$). Among the other 18 patients who had no medication and whose course was also considered uncomplicated but who were limited at the 8th week exercise test by cardiovascular signs or symptoms, 10 (56 percent) had long-term complications. This incidence was significantly greater than that in patients with a nonischemic 8 week test ($p < 0.001$). The site of myocardial infarction in these 18 patients was inferior in 61 percent, anterior in 28 percent and subendocardial in 11 percent. Four of the 13 patients with exercise-induced S-T elevation had long-term complications, but all 4 also had S-T depression.

Discussion

Features of our study group: The predominance in our series of patients with an inferior or posterior site of myocardial infarction probably reflects our exclusion of patients with clinical heart failure from the study. The preponderance of inferior myocardial infarction is similar to that in other postmyocardial infarction exercise studies.[9,11,19,20] Inferior infarction was also predominant in the 18 patients who had the highest complication rate.

Our patients were a select group with uncomplicated myocardial infarction. No patient was taking digitalis, propranolol or an antiarrhythmic agent. In all past studies there was no medication control; up to 23 percent of patients reported on were taking antiarrhythmic drugs or propranolol and up to 66 percent were taking digitalis.[7–13] These medications could exert profound effects on the presence of angina pectoris, ischemic electrocardiographic and heart rate responses, exercise duration, and presence of arrhythmias. Attrition has occurred in previous serial studies[9,10,19]; however, none occurred in out patient group.

Comparison of 3 week and 8 week exercise tests: Table V compares the age-related maximal heart rate of our patients tested 8 weeks after acute infarction with data obtained from previous exercise studies of normal subjects[21] and patients tested 3 weeks after infarction.[5] In all age decades the mean maximal heart rate in patients who have had a myocardial infarction was less than that in normal subjects.

Early after myocardial infarction, our patients had a maximal exercise performance essentially equivalent to that of patients studied more than 3 months after infarction[4,14,15] (Table VI). In our subjects, the mean maximal heart rate at 8 weeks after infarction was higher than that observed by Ibsen et al.[5] during maximal exercise treadmill testing at 3 weeks. Their results may have been influenced by the 19 percent of patients who were taking digitalis and 3 percent taking propranolol, and inclusion of patients with myocardial dysfunction.

At submaximal equivalent exercise work loads, there was no significant difference in the exercise variables studied from the 3rd to the 8th week in our reference population. This finding is at variance with that of other investigations. The study by Markiewicz et al.[9] with serial submaximal treadmill testing in 46 patients (23 of whom had symptom-limited tests) after acute myocardial infarction showed that the aerobic capacity improved from the 3rd to the 8th week. Wohl et al.[19] also

* Bruce treadmill protocol.

noted improvement early after infarction but showed a more favorable myocardial oxygen supply-demand ratio from the 3 to 6 week study to the 3 to 6 month study because of improvement in myocardial function. The exercise in approximately 50 percent of their patients was limited by symptoms and signs suggestive of myocardial ischemia at peak exercise. Many patients were taking cardiotropic agents, and patients in functional class III were included in their study. None of our patients were similarly limited, although 30 percent had signs of ischemia at peak exercise.

Ischemic changes during exercise early after infarction: Studies of exercise testing after myocardial infarction have shown that angina is produced in 9 to 21 percent of patients at 3 weeks.[3,5,6,9,10,12] Angina developed in 10 percent of our reference patients at 3 weeks and in 21 percent at 8 weeks after myocardial infarction. Abnormal S-T segment response with exercise occurs in 13 to 49 percent of patients at 3 weeks, occurring in most with maximal exercise.[3,5,6,9,10,12] One mm or more S-T segment depression was seen in only 3 percent of our reference patients at 3 weeks and in 28 percent at 8 weeks after acute myocardial infarction. No serious ischemic complications were seen in any post-infarction exercise study. Our study shows that ischemic exercise changes in patients with uncomplicated infarction are rarely present at 3 weeks after acute infarction, and that more ischemia is evident at the higher exercise work load at 8 weeks but is still unusual.

Safety and advantages of exercise testing after infarction: Modified treadmill testing at 3 weeks and maximal testing at 8 weeks after acute myocardial infarction under controlled circumstances are more safely performed than unmonitored home activity and are, in fact, desirable in the management and follow-up of patients. The 3rd week exercise test allows assessment before hospital discharge, and the 8th week test allows assessment for return to work or long-term exercise prescription. We found that the 8 week exercise test detected 18 patients (16 percent of the total group of 108) who were in a very high risk group (56 percent) for long-term complications, although their condition had previously been considered uncomplicated. Twenty-five to 29 percent of patients after uncomplicated myocardial infarction who manifested angina or S-T segment depression but were not limited by these signs or symptoms on the 8 week test had a long-term complication. However, exercise-induced S-T elevation did not help to identify patients at risk. Exercise testing allows an objective measure of capacity and, psychological reaction to physical activity as well as of possible myocardial ischemia that would otherwise go unnoticed.

Evaluation of ventricular arrhythmias: Ventricular arrhythmias after acute myocardial infarction are more accurately evaluated with continuous ambulatory monitoring than with exercise treadmill testing.[1] However, more than 600 patients have been studied with exercise to detect arrhythmias in the 2nd and 3rd weeks after acute myocardial infarction. No relation was noted in our study or in that of others between arrhythmia and either angina or S-T segment depression, except in the investigation of Markiewicz et al.[9] In previous studies[3,5,10,12,22] exercise testing detected a 29 to 60 percent incidence rate of premature ventricular complexes after acute myocardial infarction (compared with the 54 percent rate in our study). In our patients, neither the presence, nor the severity of premature ventricular complexes varied significantly from the 3rd to the 8th week after infarction. In other studies,[22,23] their frequency and complexity (in a possibly different type of population) increased between 3 and 12 weeks after acute infarction. A serious arrhythmia observed during exercise after acute infarction denotes a very abnormal response. In our study, patients who manifested premature ventricular complexes that occurred at a rate of more than 30/h on 24 hour ambulatory electrocardiographic recording, were multiform or formed couplets or ventricular tachycardia were treated after the 8th week with long-term propranolol therapy. No sudden deaths were noted in this group of 32 patients.

Prognostic value of exercise testing: Our long-term follow-up findings in patients after acute myocardial infarction extend the data from several other studies in a significant way. It is becoming known that exercise testing after acute myocardial infarction has prognostic value among patients described as free of overt heart failure or chest pain. Our data extend this

group to those with a more truly "uncomplicated" status after acute myocardial infarction, Smith et al.[12] exercised 62 patients to 60 percent of their maximal heart rate 18 days after acute myocardial infarction. Their testing influenced management in 13 patients (21 percent) (administration of antiarrhythmic or antianginal therapy or prolongation of hospitalization). In 20 of the 62 patients S-T depression developed, and in 6 (30 percent) of these either death or reinfarction occurred during a mean 21 month follow-up period, whereas these complications occurred in only 5 percent of patients without S-T segment depression. Such a group of patients who manifest S-T depression at only 60 percent of predicted maximal heart rate show significant ischemia, and this poor prognosis could have been predicted. It seems that a subset of patients, similar to our 18 patients who had a 56 percent incidence rate of complications, were selected.

Theroux et al.[24] studied 210 patients 11 days after acute myocardial infarction with treadmill testing to 70 percent of predicted maximal heart rate. Eighty-three patients were taking propranolol and 22 were taking digitalis. These investigators concluded that exercise testing could predict mortality since only 2.1 percent (3 of 146) of patients without S-T segment changes versus 27 percent (17 of 64) of those with S-T segment depression died in the subsequent year. Sudden death occurred in 1 (0.7 percent) of 146 and in 10 (16 percent) of 64 patients, respectively ($p < 0.001$). It was also significant that angina developed in 65 percent of patients with chest pain during the test but in only 36 percent of those who had no chest pain during the test. These findings also indicate that, similar to our subset of 18 patients, a significant number of their patients had ischemia 2 weeks after infarction. Thus, a clinical evaluation without objective measurements is inadequate to assess which patients are truly at lower risk.

Significant changes from the reference values given for the exercise variables, angina, S-T segment depression and ventricular arrhythmias should be identified early after myocardial infarction. The exercise response of our patients with uncomplicated myocardial infarction should serve as guidelines for recommending exercise prescriptions, antianginal and antiarrhythmic therapy and, possibly, cardiac catheterization.

A heterogeneous group of 19 consecutive patients with coronary artery disease were studied with radionuclide ventriculography before and after a mean of 6 months of exercise training. Ejection fraction was measured at rest, at matched submaximal supine work loads and during maximal supine bicycle exercise. After training there was no change in mean ejection fraction at rest or during maximal exercise, but a higher maximal mean systolic blood pressure, heart rate and work load were achieved. At equivalent submaximal work loads after training, similar levels of mean heart rate and systolic blood pressure were reached but a statistically greater mean ejection fraction was obtained. These preliminary results suggest that exercise training may improve cardiac function during exercise in selected patients with coronary disease. A randomized study using similar techniques has been initiated.

Improvement in the exercise capacity of patients with coronary artery disease after exercise training has been demonstrated.[1–3] This improvement is associated with peripheral adaptations probably due to circulatory, histologic and enzymatic alterations in the exercised muscle groups, resulting in more efficient function.[4,5] However, few data exist on the effects of training on cardiac function in human subjects, particularly on cardiac function during exertion. No difference was found in ventricular function measured during cardiac catheterization in patients with coronary artery disease before and after exercise training, but these measurements were obtained only during rest.[6–9]

Radionuclide ventriculography provides a simple noninvasive method for the assessment of left ventricular function both at rest and during exercise.[10] The purpose of this investigation was to use radionuclide ventriculography to assess ventricular performance during exercise in patients with coronary artery disease before and after an exercise training program.

Methods

Patient selection: A total of 25 consecutive patients entering our cardiac rehabilitation program who consented to evaluation before and after exercise training were studied. However, six patients were subsequently eliminated: three because the initial studies were conducted less than 3 months after myocardial infarction, two because of necessary changes in medication and one because of mitral regurgitation that made ejection fraction measurements unreliable. Pertinent characteristics of the 19 patients are presented in Table I. The mean age was 51 ± 9 years (range of 35 to 64) and the mean training time was 6 ± 2 months. Four patients had coronary arterial bypass grafting at least 4 months before the initial study. Seven patients were receiving propranolol during this period. The only other medications administrated were nitrates, which were discontinued at least 4 hours before the start of all testing procedures.

Exercise testing: Supine rest and exercise equilibrium radionuclide ventriculography was performed on an imaging table with a mounted electronically

braked bicycle ergometer (Uniwork-845T, Quinton Instruments) of adjustable height. After acquisition of images at rest, the patient's feet were strapped to the pedals at the 15° elevation. After a brief trial of supine exercise to estimate exercise capacity, exercise testing began at 1/3 the patient's estimated maximal work load. The work load was then increased to approximately 2/3 maximal capacity and finally to the estimated maximal work load. All stages were 3 minutes in duration with scintillation data collected during the last 2 minutes of each stage. Heart rate, blood pressure and the electrocardiogram were carefully monitored and recorded at each stage. Exercise was terminated in most patients at the point of volitional fatigue. However, two patients stopped without symptoms because of 0.3 mV S-T segment depression and four stopped with the onset of definite anginal pain.

Treadmill testing was performed in close proximity (usually 2 weeks) to the radionuclide ventriculographic studies, with use of a modified Balke-Ware protocol.[11] Treadmill speed was 2.0 or 3.3 miles/h with the grade increased 5 percent every 2 or 3 minutes. Termination of the test and acquisition of hemodynamic and electrocardiographic data were the same as for the radionuclide ventriculographic test. Maximal oxygen consumption was estimated from the maximal speed and grade attained, as previously validated.[11]

Equilibrium radionuclide ventriculography: Fifteen to 25 millicuries (mCi) of technetium-99m tagged to human serum albumin was introduced through a catheter in an antecubital vein. Imaging was performed for 5 minutes with the patient supine at rest, and then for 2 minutes during exercise, with use of a modified left anterior oblique camera position with a 10 to 15° caudal tilt. This positioning allowed optimal right and left ventricular and atrioventricular separation. Data were recorded with a mobile single crystal scintillation camera (Picker "Dynamo") equipped with a general purpose parallel hole collimator and processed on a Medical Data Systems PAD computer. The peak of the R wave was used as the physiologic gate. The computer divided the R-R interval into 28 equal time periods (frames) and then assembled data from all of the cardiac cycles in the given acquisition period. The viewer was then able to select the left ventricular region of interest by placing a box around the left ventricle at end-diastole. A computer algorithm based on a combination of the decline of count rate and its second derivative automatically determined the left ventricular border. Generation of a time-activity curve was accomplished by determining the left ventricular counts for each frame corrected for background activity in the left lung. With use of the time-activity curve, ejection fraction (EF) was calculated using the formula: EF = EDC − ESC/EDC, where EDC = left ventricular counts at end-diastole and ESC = left ventricular counts at end-systole. This technique has been validated and shown to be highly reproducible at rest and during exercise in our laboratory.[12,13]

The lowest ejection fraction at rest obtained in our laboratory for a normal person has been 0.53.[14,15] We therefore selected an ejection fraction of less than 0.50 to indicate left ventricular dysfunction at rest. The lowest percent change in ejection fraction (EF) from rest to maximal supine exercise ([exercise EF − rest EF] ÷ rest EF × 100) in normal subjects has been 11 percent. Therefore, we consider any percent change less than this to be consistent with exercise-induced ischemic left ventricular dysfunction.[14,15]

Exercise training program: After the initial treadmill test, an exercise prescription was given with intensities ranging from 65 to 85 percent of the estimated maximal oxygen consumption. Exercise sessions were conducted on Monday, Wednesday and Friday in an electrocardiographic monitored class. The classes consisted of 10 minutes of warm-up, six 5 minute exercise periods on various aerobic exercise devices separated by 2 minute rest intervals, and cool-down activities conducted for an additional 10 minutes. The training activities included treadmill walking, bicycle pedaling, use of an arm ergometers, step climbing, rowing and light lifting.

After completion of monitored training sessions, usually after 3 months, patients were graduated to a walk-jog program either outdoors or in a hospital gymnasium. Warm-up and cool-down activities were similar to those used in the monitored classes. However, aerobic conditioning was accom-

plished by 30 minutes of continuous walking or jogging, or both. Periodic electrocardiographic, blood pressure and symptomatic assessments were conducted to detect possible contraindications to exercise and to reassess the exercise prescription. No medical complications were observed in any of our patients.

This study was approved by the University of California, San Diego Human Subjects Committee and informed consent was obtained from each patient before any procedures were performed. Statistical testing was done using paired *t* tests.

Results

Resting data (Table II, Fig. 1): There was no change in the mean ejection fraction at rest after exercise training (0.57 ± 0.13 before training versus 0.55 ± 0.13 after training). Of the 19 patients studied, 13 had a normal ejection fraction at rest (0.50 or greater) and 6 had an abnormal ejection fraction at rest. Ejection fractions at rest ranged widely, from a low of 0.31 to a high of 0.81. After training, an abnormal ejection fraction reverted to normal in only one patient and a normal value became abnormal in two patients.

Submaximal exercise data: Scintillation data at matched submaximal work loads were obtained in 16 of the 19 patients before and after exercise training (Tables II and III). We were unable to obtain data at submaximal work loads in three patients because of technical problems. There was no significant difference in the mean submaximal rate-pressure product (product of systolic blood pressure and heart rate) attained during the submaximal work load before and after training ($164 \pm 27 \times 10^2$ versus $164 \pm 33 \times 10^2$). The submaximal systolic blood pressure could not be accurately recorded in one patient before training. The ejection fraction response to these matched submaximal work loads is shown in Table II and Figure 1. After training, there was a significant increase in the mean submaximal ejection fraction (0.55 ± 0.12 before versus 0.59 ± 0.13 after training). Among the 16 patients evaluated at matched submaximal work loads, the ejection fraction increased by 0.04 or more in 8, decreased in 1 and remained unchanged in 7 after exercise training.

Maximal supine bicycle exercise data: The 19 patients demonstrated no significant increase in mean heart rate after exercise training (Table III). However, maximal systolic blood pressure (174 ± 25 before versus

184 ± 24 after training) and rate-pressure product (223 ± 57 × 10^2 before versus 246 ± 69 × 10^2 after training) were significantly increased after training. In addition, the patients attained a greater mean maximal work load after the training program (661 ± 172 kpm before versus 768 ± 229 kpm after training). In 13 patients the peak work load increased after training; in 5 it remained unchanged and in only 1 it decreased.

The mean maximal ejection fraction did not change after exercise training (0.56 ± 0.13 before versus 0.56 ± 0.16 after training) at the higher mean rate pressure product and work load (Tables II and III). Maximal ejection fraction increased by 0.04 or more in seven, decreased in six and did not change in six after exercise training.

Change in ejection fraction from rest to maximal exercise: The increase in the mean percent change in ejection fraction from rest to maximal supine bicycle exercise was also not significant (−2.3 ± 13 percent before versus 2.5 ± 19 percent after training) (Fig. 2, Table II). In 11 patients the percent change in ejection fraction increased and in 8 it decreased after exercise training. However, if a normal response to supine bicycle exercise was considered to be a percent change of 10 percent or more, the ejection fraction response to supine bicycle exercise after exercise training normalized in 7 patients, remained unchanged in 11 and became abnormal in only 1. All seven patients whose ejection fraction response normalized showed an increase in absolute maximal ejection fraction after training, but some of them also showed a decrease in ejection fraction at rest. Among the 12 patients whose ejection fraction response did not normalize (there was no change in 11 and in 1 the response became abnormal after training),

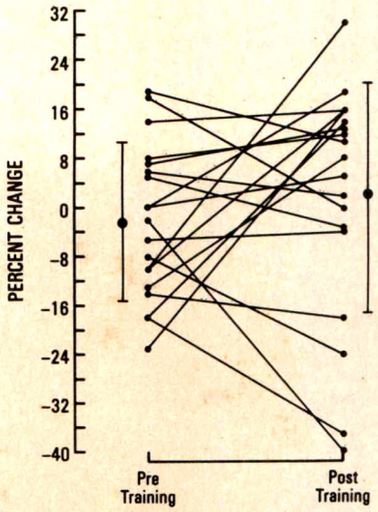

FIGURE 2. Percent change in ejection fraction from rest to peak exercise before (Pre) and after (Post) exercise training.

10 attained either a greater rate-pressure product or a greater maximal work load after training. Seven of these 10 patients attained both higher values for both rate-pressure product and work load after training.

Treadmill test data (Table IV): The training effect of the exercise program was evaluated by comparing mean heart rate, systolic blood pressure, rate-pressure product and estimated maximal oxygen consumption with treadmill tests performed before and after the training program. A training effect was demonstrated by a significant increase in mean estimated maximal oxygen consumption (31 ± 8 before versus 37 ± 9 cc/

kg-min after training), a lower mean rate pressure product ($190 \pm 44 \times 10^2$ before versus $165 \pm 23 \times 10^2$ after training) and a lower mean heart rate (121 ± 13 before versus 111 ± 13 after training) at a matched submaximal treadmill speed and grade.

Discussion

Experimental documentation of cardiac effects of exercise training: Animal studies[16,17] have provided strong evidence supporting the hypothesis that left ventricular function can be improved with exercise training. Bersohn and Scheuer[18] studied the effects of long-term exercise on the rat heart. Exercised rats and control rats were killed and their hearts perfused under aerobic and ischemic conditions. Coronary blood flow was reduced by 40 percent to produce ischemia, and measurements were made in both trained and untrained rat hearts at equivalent levels of myocardial oxygen consumption. Increased left ventricular pressure, a 30 percent greater stroke volume, prolonged diastole and faster relaxation were reported for hearts of exercise-trained rats during ischemic conditions. Under normal conditions, the trained rat hearts exhibited a longer diastolic phase and faster relaxation than did the untrained rat hearts. In another study,[19] these investigators demonstrated enhanced ejection fraction, circumferential fiber work, cardiac output and stroke work in trained rats. Improved myocardial contractility has also been shown[20] to occur in dogs after exercise training by plotting the first derivative of ventricular pressure (dP/dt) as a function of heart rate. Although not all animal studies have found augmented left ventricular function after exercise training,[21] most studies have shown that on a long-term basis exercised young animals demonstrate enhanced cardiac function.

Echocardiographic assessment of effects of exercise training: Echocardiography has been used to assess the effects of training on chamber size, left ventricular wall thickness and resting left ventricular function in human subjects. Longitudinal studies comparing echocardiographic measurements made before and after training have yielded conflicting results. Ehsani et al.[22] reported a rapid increase in left ventricular volume and mass in healthy young adults after a swimming program. These dimensional changes occurred in less than 5 weeks, but no changes were found in the ejection fraction at rest. DeMaria et al.[23] found similar results including increases in left ventricular end-diastolic dimension, stroke volume and shortening fraction after exercise training in 24 healthy adults. Using radionuclide ventriculography, Sheps et al.[24] found in six normal men an increase in ejection fraction at rest at the same basal heart rate after training. Stein et al.[25] were the only investigators to study training-induced changes in ejection fraction during semisupine exercise using echocardiography and found that ejection fraction increased in healthy college students after an exercise program. Wolfe et al.[26] studied middle-aged men and found a moderate increase in stroke volume at rest due to an increase in end-diastolic dimension secondary to a longer ventricular filling time. However they found no change in left ventricular structure or resting contractile state. Other investigators[27–29] have also been unable to document morphologic or functional changes. Most echocardiographic studies[30–32] comparing athletes with sedentary subjects have found no significant difference in left ventricular function at rest

The inconsistencies in these studies demonstrate the difficulty in finding changes in ventricular function or dimensions after exercise training. This is particularly the case in older subjects and when using low levels of training.

Other clinical physiologic studies in exercise training: A controlled study examining cardiovascular adjustments accompanying exercise training in patients after myocardial infarction was recently conducted by Paterson et al.[33] These investigators randomly assigned 79 patients to an exercise group of either high or low intensity and followed them up for 1 year. During exercise testing, they found an augmented arteriovenous oxygen difference at 6 months and an increase in stroke volume at 12 months in the high intensity group only. The early study of Frick[34] also found improved exercise stroke volume in patients undergoing exercise training. The increased exercise stroke volume in these two studies suggests cardiac adaptations to long-term exercise and illustrates the importance of evaluating changes during exertion rather than at rest.

Data obtained during cardiac catheterization using contrast ventriculography[6–9] have shown no change in left ventricular regional or global function at rest in patients with coronary artery disease before and after exercise training. These angiographic studies have used left ventricular ejection fraction as the best means of evaluating the contractile performance of the heart at rest. Such studies are difficult to perform during exercise because of technical difficulties in adequately opacifying the ventricular cavity.

Left ventricular function after training studied with radionuclide angiography: The use of radionuclide ventriculography made it possible to assess noninvasively the response of left ventricular ejection fraction not only at rest but also during exercise in our 19 patients. Consistent with previous results utilizing cardiac catheterization,[6–9] no significant change in mean resting ejection fraction was found in our patients after training. When radionuclide ventriculography was used in patients before and after coronary arterial bypass grafting, ejection fraction at rest was not changed.[35]

The contractile state of the heart during equivalent submaximal exercise was assessed in 16 of our 19 patients who performed the same submaximal work load during supine bicycle exercise before and after training. There was a significant increase in submaximal ejection fraction after training. This occurred at the same level of myocardial oxygen demand, as reflected by rate-pressure product,[36] and at the same bicycle work load. Submaximal ejection fraction before and after training has not previously been studied. However, in patients who had clinical improvement after coronary arterial bypass grafting, Kent et al.[35] demonstrated increased ejection fraction and fewer exercise-induced wall motion abnormalities at the same work load as that performed preoperatively.

There was no reduction in heart rate or systolic blood pressure at matched submaximal supine bicycle work loads after training. These findings could be due either to the specificity of training (because patients were tested in the supine position but were exercised in the erect position only) or to positional ventricular volume differences.

Mean ejection fraction obtained at maximal exercise showed no change after exercise training. An increase in ejection fraction at maximal work load was inhibited by the greater myocardial oxygen demand reflected by the higher maximal rate-pressure product and work load attained after training. There was also no significant increase in the mean percent change in ejection fraction from rest to maximal exercise after training. However, in seven of our patients this ejection fraction response normalized and in only one did it become abnormal after the exercise training program. We were careful to eliminate from the investigation patients who were initially studied less than 3 months after myocardial infarction as well as those who had mitral regurgitation or required medication that might affect the exercise tests. We have noticed spontaneous improvement in ejection fraction in patients as they recover from a myocardial infarction or while they are taking nitroglycerin or propranolol, or both.[37,38]

Correlation with clinical state: Our study group is heterogeneous because of the small number of consecutive patients studied and the types of patients that present to an outpatient exercise program. For this reason we were unable to detect trends in the data relating the ejection fraction responses to clinical information or other exercise test responses. Attempts at multivariate analysis resulted in too few subjects in each classification to make meaningful conclusions.

Four patients joined our program after coronary bypass grafting. There was no significant change in their mean (0.57 before versus 0.55 after training) ejection fraction or peak (0.59 before versus 0.62 after training) exercise ejection fraction at rest, but three of the four patients had an increase in submaximal ejection fraction. This change, together with an increase in estimated maximal oxygen consumption (32 cc O_2/kg-min before versus 38 after training), support the conclusion of Oldridge et al.[39] that exercise training can be beneficial to patients after coronary bypass surgery. Our observations are also consistent with those of Paterson et al.,[33] who were unable to correlate improved exercise stroke volume after training to initial or final clinical status. In addition, Lee et al.[40] found no correlation between increased work capacity and left ventricular function after exercise training.

Bruce et al.[41] used invasive techniques before and after exercise training to study 10 patients with coronary disease. Although the condition of all was improved, some of the patients showed a definite decline in exercise cardiac output and stroke volume, a deterioration that could have been secondary to progression of disease or to their exercise program. This finding points out the need to develop noninvasive techniques to identify such patients.

Rate-pressure product has been demonstrated to be an accurate estimate of myocardial oxygen demand during exercise.[36] Because it is doubtful that there would be a decrease in end-diastolic volume after training in these patients, the ejection fraction response may reflect an adaptive increase in left ventricular

contractility at the same or a greater myocardial oxygen consumption, improvement in myocardial microcirculation or reduced coronary flow requirements. Therefore, it appears that, like peripheral muscle, cardiac muscle may become more efficient after training. Future exercise training studies need to include measurement of left ventricular volume[42] and other measures of ventricular contractility[43] and to include assessment of myocardial perfusion.[44,45]

Clinical implications: Concomitant with the peripheral adaptations demonstrated in patients with coronary artery disease responding to exercise training, selected patients may also demonstrate augmented left ventricular function during exercise. However, reports[44,45] have emphasized the importance of considering spontaneous improvement in function after a myocardial infarction. For this reason, randomized larger studies considering left ventricular function and perfusion, exercise capacity, severity of disease and clinical status are needed to document our preliminary findings and to assess which patients respond most favorably to exercise training as a mode of therapy. Perhaps even those who are likely to have an adverse hemodynamic response can be identified. Currently at this institution such a study, called PERFEXT (an acronym for perfusion and performance exercise trial), is being sponsored by the National Institutes of Health, Bethesda, Maryland.

Relation of Exercise-Induced Physiologic S-T Segment Depression to R Wave Amplitude in Normal Subjects

MYRON C. GERSON, MD
STEPHEN N. MORRIS, MD, FACC
PAUL L. McHENRY, MD, FACC

Indianapolis, Indiana

Exercise electrocardiography was performed in 100 asymptomatic male volunteers with a mean age of 42.6 years. The R wave and total RS amplitude and the magnitude of physiologic S-T segment depression at the J junction were quantitated for a modified bipolar CC_5 lead and a vertically oriented bipolar lead (VL) using computer-averaged groups of 25 consecutive QRS complexes from each of seven stages of rest and exercise. Computer-generated X-Y plots were used to examine the correlations between the magnitude of S-T depression and the R wave and total RS amplitudes. The magnitude of S-T depression and of the R wave amplitude were unrelated at standing rest but showed increasing correlation with progressive increases in exercise heart rate (correlation coefficient = 0.425, $p < 0.00001$ at maximal exercise). The total RS amplitude was also related to the magnitude of S-T depression during exercise, but the correlations did not improve progressively with increases in exercise heart rate. The magnitude of S-T depression was more closely related to R wave amplitude and total RS amplitude in the vertically oriented lead than in the CC_5 lead.

These data demonstrate a significant relation between the magnitude of R wave and total RS amplitudes and the magnitude of physiologic S-T segment depression in normal subjects during exercise. They suggest the need for evaluation of S-T depression corrected for R wave amplitude in an attempt to improve the diagnostic accuracy of the exercise electrocardiogram. The data also suggest that the criteria for abnormal S-T depression should take into consideration the different R wave voltages reflected by different types of recording leads.

From the Krannert Institute of Cardiology, the Department of Medicine, Indiana University School of Medicine, and the Veterans Administration Hospital, Indianapolis, Indiana. This study was performed during Dr. Gerson's tenure as a U.S. Public Health Service Trainee in Cardiology and was supported in part by the Herman C. Krannert Fund, Indianapolis,Indiana; Grants HL-06308 and HL-07182 from the National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, Maryland; the American Heart Association, Dallas, Texas; and the American Heart Association, Indiana Affiliate, Inc., Indianapolis, Indiana. Manuscript received January 8, 1980; revised manuscript received May 19, 1980, accepted May 30, 1980.

The clinical utility of the diagnostic exercise electrocardiogram is fundamentally based on changes that occur in the S-T segment in response to increasing work loads and heart rates. The depth of S-T segment depression is one of the measurements used to identify patients with clinically significant coronary artery disease. In normal subjects some degree of depression is usually seen in the early portions of the S-T segment during exercise, and the clinical differentiation between a normal and an abnormal response largely depends on the magnitude and contour of the S-T depression. The mechanisms and correlates of physiologic S-T depression in normal subjects have not been clearly established. The purpose of this study was to determine whether a relation exists between the electrocardiographic R wave amplitude and the degree of exercise-induced S-T segment depression during exercise in normal subjects.

Methods

Study subjects: The study group consisted of 100 asymptomatic and presumably healthy male members of the Indiana State Police Force. The mean age was 42.6 years (range 32 to 55). No study subject was receiving antiarrhythmic drugs, propranolol or a digitalis glycoside, and none had diastolic blood pressure of 90 mm Hg or more at rest. All subjects had a normal 12 lead electrocardiogram at rest and none demonstrated S-T segment depression on the bipolar monitor leads before exercise.

Exercise test protocol: Treadmill exercise was performed with use of a modified Balke protocol.[1] The exercise electrocardiogram was continuously monitored using a modified bipolar CC_5 lead and a vertically oriented bipolar lead (VL) that simulates lead II of the standard electrocardiogram. Placement of the exploring electrode for the modified CC_5 lead varied from the V_4 to V_6 position in any given subject so as to obtain a maximal R wave amplitude. However, care was taken to choose an electrode position that also yielded a complex with a small S wave.[1] The exploring electrode for the bipolar vertical lead was placed at the lower left costal margin in the mid axillary line and the corresponding negative electrode was placed on the forehead. All exercise tests were performed under the direct supervision of a physician and were terminated when the subjects reached their symptom-limited work load. No subject experienced chest pain. The maximal heart rates achieved ranged from 142 to 214 beats/min; the mean maximal heart rate was 177.5 beats/min. All but one subject achieved greater than 85 percent of his age-predicted maximal heart rate.

Analysis of exercise test data: The exercise electrocardiogram was continuously recorded on magnetic tape using a Hewlett-Packard 3964A recorder. A time code was simultaneously generated and recorded on one channel of the tape recorder so that selected intervals of the electrocardiographic data could be subsequently located for computer averaging.[1] For this study 25 consecutive QRS complexes were selected from the period of standing rest, from two submaximal exercise periods (heart rates approximately 120 and 140 beats/min, respectively), from maximal exercise, from the onset of recovery and from the 3 and 6 minute recovery periods. The analog data were converted to a digital format at a frequency of 500 samples/s and a Data General Corporation Nova 2–10 computer was used for computer-averaging of the QRS complex.[1] The computer was programmed to locate the peak of the R wave of the averaged QRS complex, and an isoelectric interval was then identified within the 35 data points (70 ms) preceding that peak. The isoelectric interval, defined as the 10 ms interval with the least slope, served as the baseline for computation of the R wave amplitude in millivolts (Fig. 1). The 10 ms interval in the S-T segment starting at 60 ms beyond the peak of the R wave was used to compute the S-T level in millivolts relative to the isoelectric interval. The nadir of the S wave was identified as the most negative point in the averaged QRS complex occurring within a 40 ms interval after the peak of the R wave, and the total RS amplitude was computed in millivolts using this point and the R wave peak (Fig. 1).

Six patients had significant widening of the QRS complex during exercise that resulted in erroneous computer localization of the S-T segment interval within the terminal QRS complex. These six subjects, identified through the plots of the averaged QRS complexes, were omitted from the study.

Statistical analysis: The relation of R wave amplitude to the magnitude of computer-averaged S-T segment depression was then graphically plotted for the study group of 94 subjects for each of the seven stages of rest, exercise and recovery. Figure 2 shows a representative plot of physiologic S-T depression versus R wave amplitude recorded in the vertical lead during maximal exercise. A correlation coefficient (r value) was computed for each plot, and the significance of the relation between the R wave amplitude and the magnitude of S-T depression for each stage of exercise was assessed using the test for significance of correlation coefficients. Similar plots and data analyses were generated correlating the total RS amplitude to the magnitude of S-T depression for each stage of exercise.

Results

Correlation of R wave amplitude and S-T depression (Table I): Figure 3 shows a series of correlation coefficients (r) relating the electrocardiographic R wave amplitude to the magnitude of S-T segment depression in the two recorded leads at various stages of rest and exercise. At standing rest, the correlation coefficient between R wave amplitude and the magnitude of S-T depression was small and not statistically significant in either lead. With exercise, a statistically significant relation existed for all stages of exercise and recovery between the R wave amplitude and the magnitude of S-T depression in both leads. In the CC_5 lead the relation became significant at a heart rate of 120 beats/min and the r value increased progressively with increasing heart rates, reaching 0.425 at maximal exercise. The relation between R wave amplitude and S-T depression in the CC_5 lead during maximal exercise was described by a slope of −0.36 and an intercept of 1.3. The significant relation between these variables in lead CC_5 continued during the 3 and 6 minute recovery periods. In the vertically oriented lead there was a significant correlation between the two variables at an exercise heart rate of 120 beats/min (Fig. 3). This correlation increased with progressive exercise, the r value becoming 0.564 at maximal exercise (slope −0.57, intercept 2.1). Correlation coefficients during all stages of exercise and recovery periods were statistically significant ($p < 0.001$).

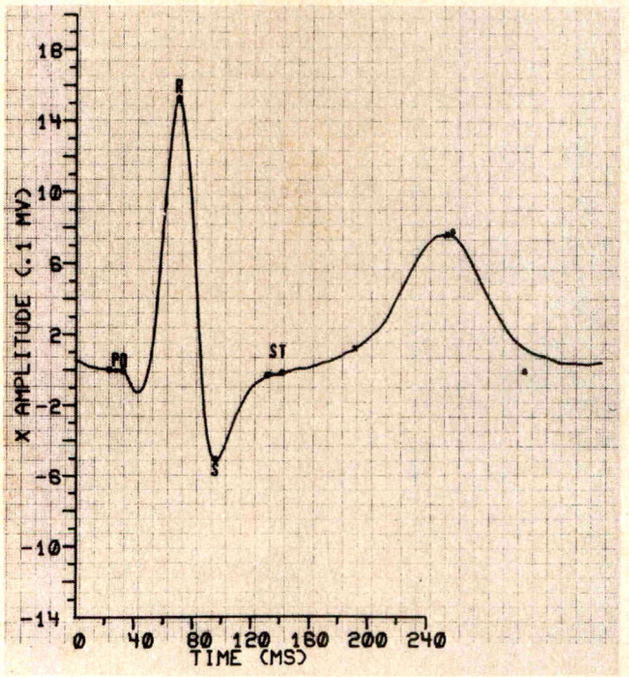

FIGURE 1. Electrocardiographic QRS as derived by computer-averaging of 25 complexes. Sample reference points for the calculation of electrocardiographic wave amplitudes are demonstrated. MS = milliseconds; MV = millivolts; PQ = 10 ms isoelectric interval; R = peak of R wave; S = nadir of S wave; ST = 10 ms interval for measurement of S-T level.

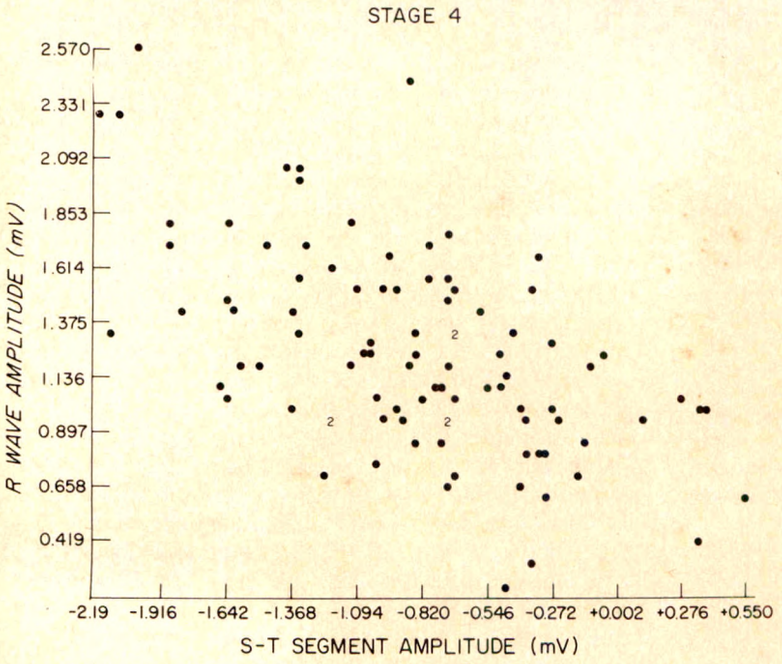

FIGURE 2. Scattergram demonstrating the magnitude c physiologic S-T segment depression versus the magni tude of R wave amplitude in the vertical lead durin maximal exercise (stage 4)

Correlation of total RS amplitude and S-T depression (Table I): Figure 4 illustrates a series of correlation coefficients for the different stages of rest and exercise correlating the total RS amplitude with the magnitude of S-T segment depression. At standing rest there was no significant relation between the RS amplitude and the magnitude of S-T depression in the CC_5 lead. A weak relation was present in the vertical lead ($r = 0.179$, $p < 0.05$) at standing rest. With exercise, the S-T depression was significantly related to the RS amplitude in both leads at all stages of exercise and recovery. Unlike the correlation of R wave amplitude to S-T depression, the relation between the total RS amplitude and the magnitude of S-T depression did not increase progressively as the exercise heart rate increased.

Discussion

S-T segment depression during exercise in normal subjects: The major variable of measurement ir diagnostic exercise electrocardiography is the magni tude of depression of the S-T segment. However, S-T depression also occurs in normal subjects during exercise,[2] a finding that often limits the diagnostic speci ficity of the exercise electrocardiogram. The problem of S-T depression in normal subjects is generally ap proached by considering the slope or rate of rise of the S-T segment. The S-T depression observed in norma subjects during exercise is thought to be in part due to an increase in the magnitude of the atrial repolarization wave (Ta wave)[3] combined with shortening of the QRS interval,[4] and the J point and initial portion of the S-T segment are primarily altered. These physiologic al

TABLE I

Mean Values (mV) of R Wave Amplitude, RS Amplitude and S-T Segment Depression During Seven Stages of Rest, Exercise and Recovery in 94 Subjects

		Submaximal Heart Rate			Recovery		
	Standing Rest	120 Beats/ Min	140 Beats/ Min	Maximal Exercise Heart Rate*	Immediate	3 Min	6 Min
CC5 lead

* Mean 178 beats/min.

terations result in upsloping S-T depression that can usually be differentiated from the more horizontal or even downsloping S-T depression of exercise-induced myocardial ischemia. Consideration of the S-T segment slope has proved useful in the clinical interpretation of S-T depression, but the occurrence of depressed S-T segments in normal subjects remains a problem, especially when one attempts to apply slow upsloping S-T segment criteria.[5,6] Further understanding of the electrocardiographic correlates of exercise-induced S-T depression in normal subjects may prove helpful in separating normal from abnormal S-T segment responses.

Correlation of R wave amplitude and magnitude of S-T depression during exercise in normal subjects: Blackburn et al.[7] found no significant correlation between the amplitude of the R wave (lead CM_5) and the magnitude of S-T segment depression at rest in patients with heart disease. Our study found a similar lack of correlation between these two in normal subjects at rest, although there was a direct relation between the magnitude of S-T depression and the amplitude of the R wave during exercise in these subjects. The correlation between R wave amplitude and the magnitude of S-T depression increased progressively with increasing heart rates up through maximal exercise. When the total RS amplitude was compared with the magnitude of S-T depression for each stage of exercise, a lesser correlation was observed, and the correlation was not enhanced as the heart rate during exercise increased. The depth of the S wave progressively increases during increasing levels of exercise in normal subjects[8,9] (Table I), and it is possible that the relation between the S wave and the S-T segment vectors is the reverse of that of the R wave and these vectors.

Other factors influencing magnitude of S-T depression during exercise: Our study demonstrates that the magnitude of the S-T segment depression during exercise is related to the R wave amplitude in normal subjects. However, the correlation coefficients are relatively weak and other independent factors obviously influence the depth of S-T depression. One factor that may limit the correlation between R wave amplitude and S-T depression is the decrease in R wave amplitude that occurs in normal subjects during exercise.[8–10] The greatest decrease in R wave amplitude occurs at or near maximal exercise at a time when the S-T depression is greatest (Table I). The correlation coefficients could also have been adversely influenced by our computer quantitation program, which uses a fixed 10 ms interval starting at 60 ms after the peak of the R wave to compute S-T depression. As the QRS complex narrows in response to exercise,[4] this interval will be displaced further into the S-T segment; depending on the rate of rise or slope of the S-T segment, the computed S-T depression may be significantly less than the value that would be obtained if all measurements were made in the same area of the proximal S-T segment.

Role of different electrocardiographic lead systems: In our study the R wave and the S-T segment

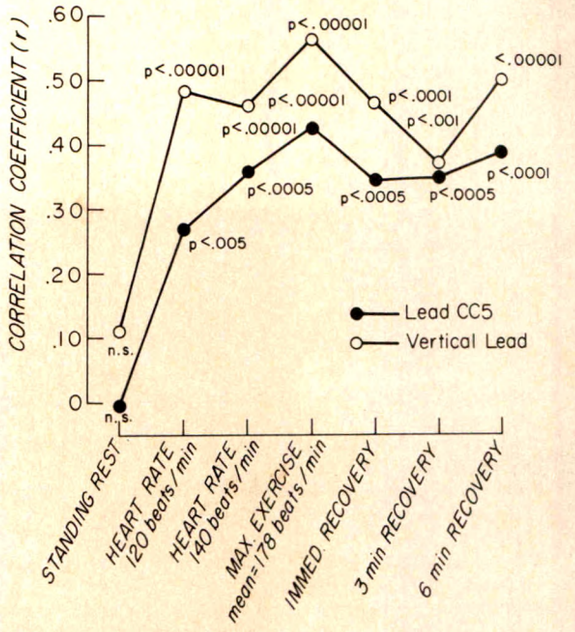

FIGURE 3. Correlation coefficients relating R wave amplitude to the magnitude of S-T segment depression at different stages of exercise. IMMED. = immediate; MAX. = maximal; n.s. = not significant; p = probability.

were more closely related in the vertical lead than in the modified CC_5 lead. A more vertically oriented bipolar V_5 lead such as CM_5 might also demonstrate a closer relation between the R wave amplitude and the magnitude of S-T segment depression than lead CC_5 because the R wave amplitude is taller in lead CM_5.[11] Computer quantitation studies by Froelicher et al.[11]

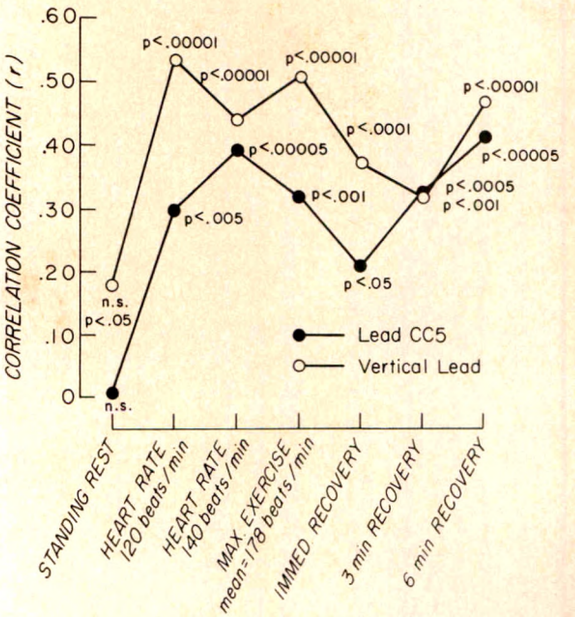

FIGURE 4. Correlation coefficients relating R wave amplitude plus S wave depth to the magnitude of S-T segment depression at different stages of exercise. Abbreviations as in Figure 3.

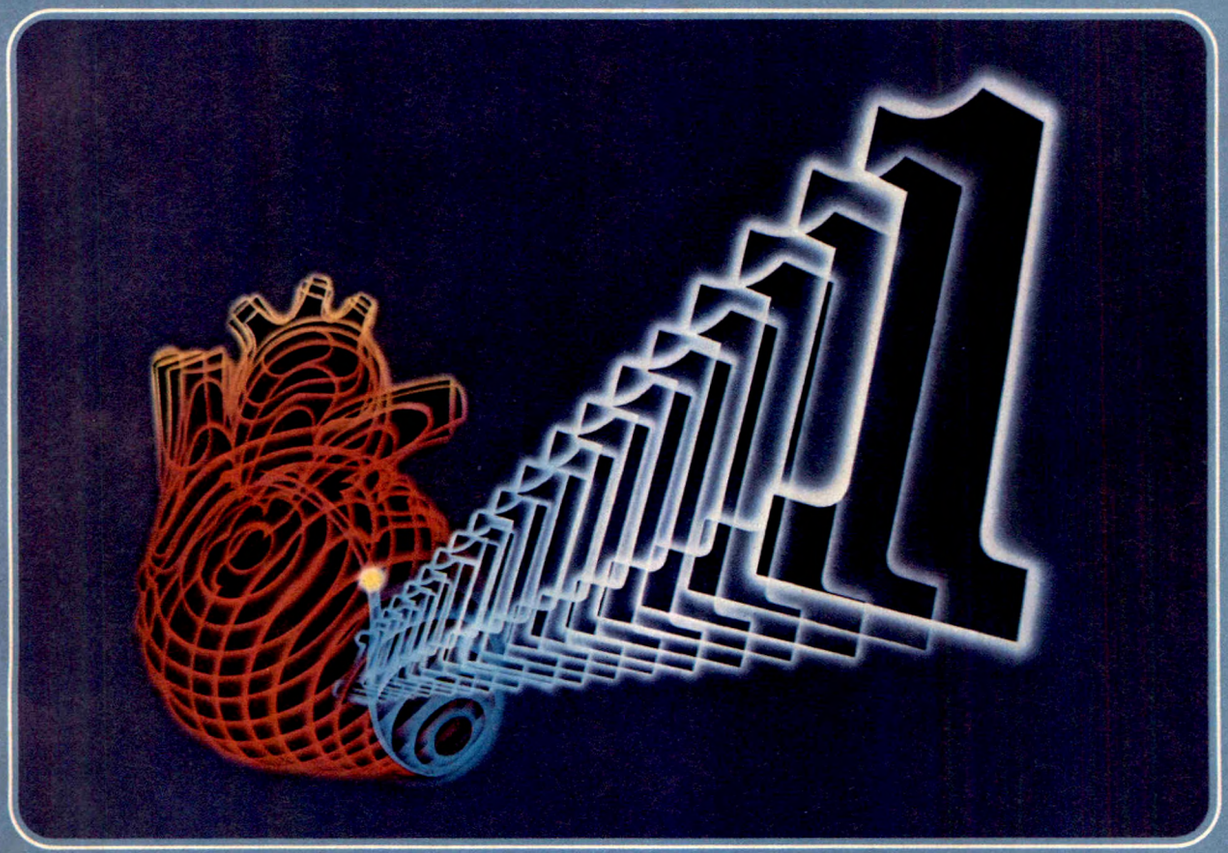

found that the magnitude of S-T depression was greater in lead CM_5 than in leads V_5 or CC_5 in the postexercise period in patients with abnormal S-T segment responses to exercise. They suggested that different criteria may have to be defined for different electrocardiographic leads if repolarization changes in these leads are to have comparable diagnostic significance.

Implications: By demonstrating a significant relation between the amplitude of the R wave and the magnitude of physiologic S-T segment depression during exercise, our study raises the possibility that the sensitivity and specificity of the exercise electrocardiogram can be improved by correcting the amount of S-T depression for the magnitude of R wave amplitude. The study also suggests the need to modify the criteria for abnormal S-T depression depending on the type of lead system used and the magnitude of the R wave reflected in that lead.

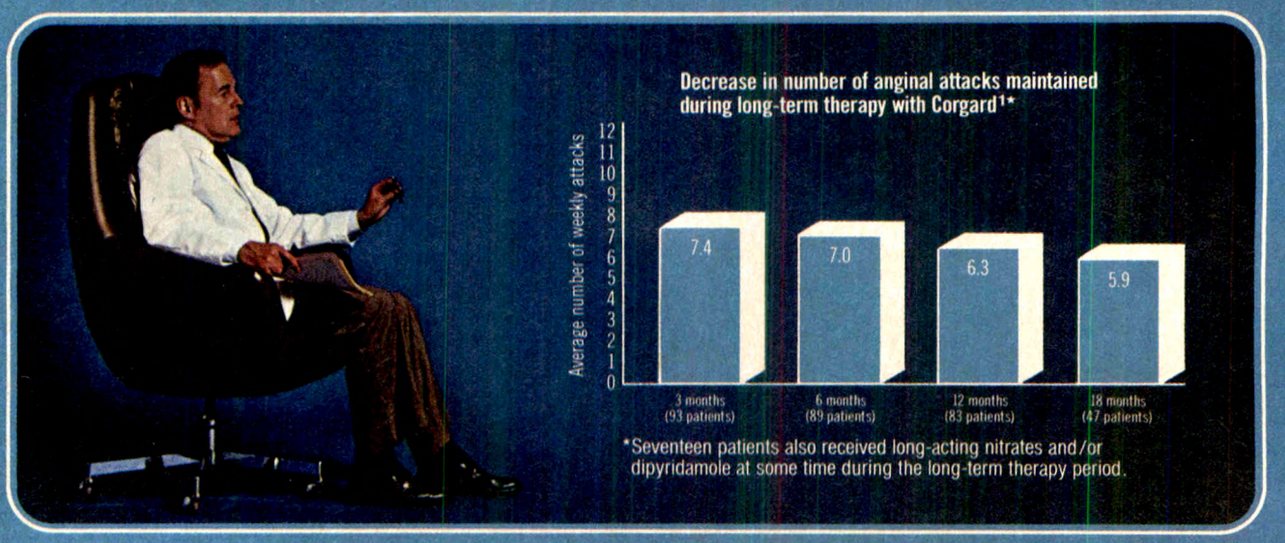
CORGARD®
nadolol tablets



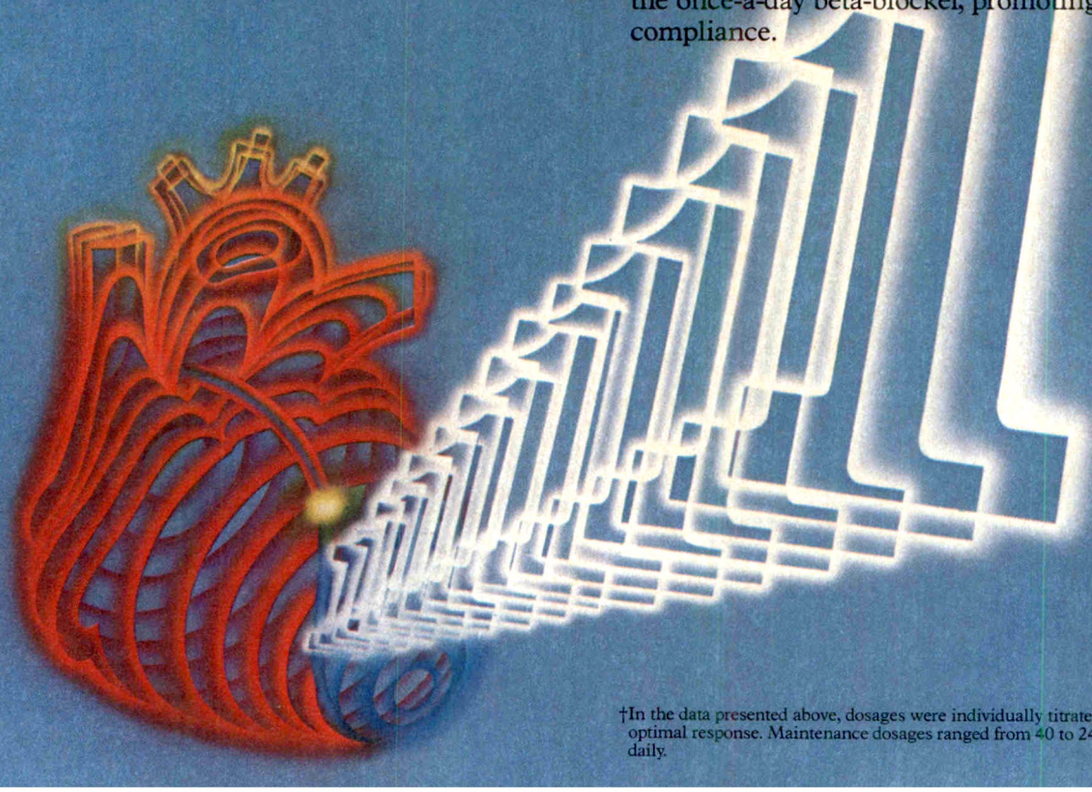
The first and only beta-blocker with once-a-day dosage

In the treatment of angina pectoris

SQUIBB

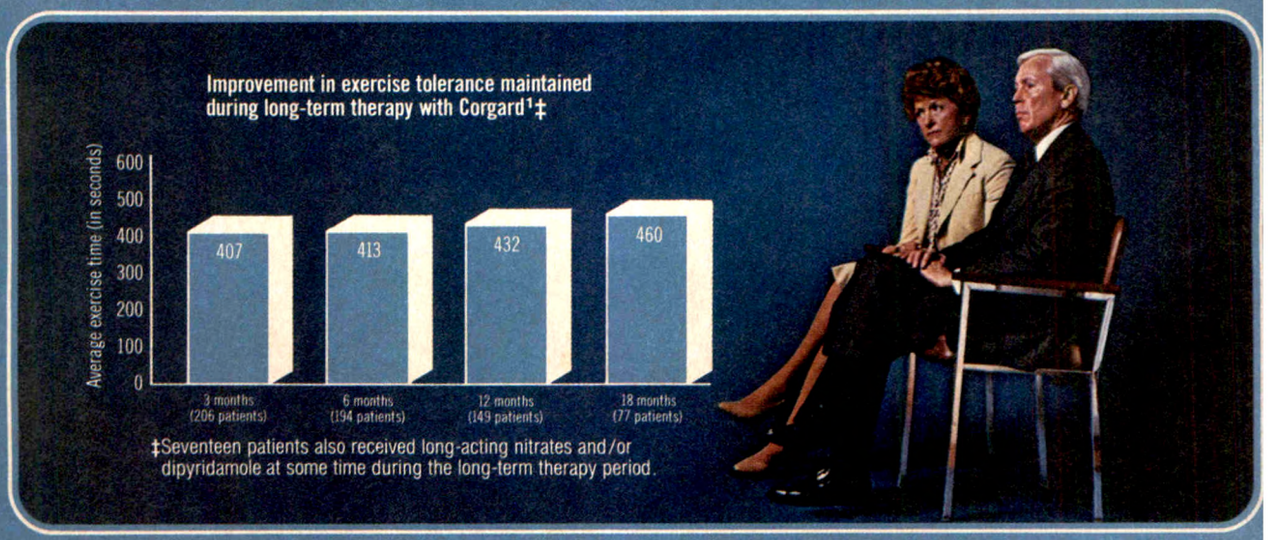
See last page of this advertisement for brief summary.

*Seventeen patients also received long-acting nitrates and/or dipyridamole at some time during the long-term therapy period.



CORGARD® [nadolol tablets]:

Once-a-day, everyday, Corgard offers round-the-clock protection



A single daily dose of Corgard offers prophylaxis in angina pectoris, helping to protect the patient all day and all night from painful attacks. And in extended clinical studies, the efficacy of Corgard — as demonstrated by a decreased rate of anginal attacks and an increase in exercise tolerance — was maintained.[1]

Once-a-day, everyday, Corgard decreases the frequency of anginal attacks

Corgard taken just once daily offers round-the-clock protection from angina pain. In one short-term study, Corgard, once a day, decreased the average number of anginal attacks per week in 115 patients with angina, from 13.6 pretherapy to 6.4 at the end of 14 weeks of therapy, a mean decrease of 59%.[1†] In 19% of the 115 patients, anginal attacks were completely eliminated. And the long half-life (20 to 24 hours) makes Corgard the once-a-day beta-blocker, promoting patient compliance.

†In the data presented above, dosages were individually titrated to achieve optimal response. Maintenance dosages ranged from 40 to 240 mg Corgard daily.

Effective control of angina pectoris

Once-a-day, everyday, Corgard increases exercise tolerance

Corgard allows the angina patient to do more. In 147 patients in the same short-term study as the one at left, Corgard, once a day, increased ergometry time by 25%, improving exercise tolerance from an average of 365 seconds pretherapy to 427 seconds at the end of 14 weeks of therapy.[1] In 21% of the 147 patients, the end point of exercise was fatigue rather than angina pain. And the single daily dose of Corgard can be taken at the patient's convenience, without regard to meals.

Once-a-day, everyday, Corgard decreases nitroglycerin usage[1]

Corgard blocks catecholamine influence on myocardial activity, decreases myocardial oxygen demand, and does not have a direct myocardial depressant effect.

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 1 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval — see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, or 120 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® single-dose packs of 100 tablets.

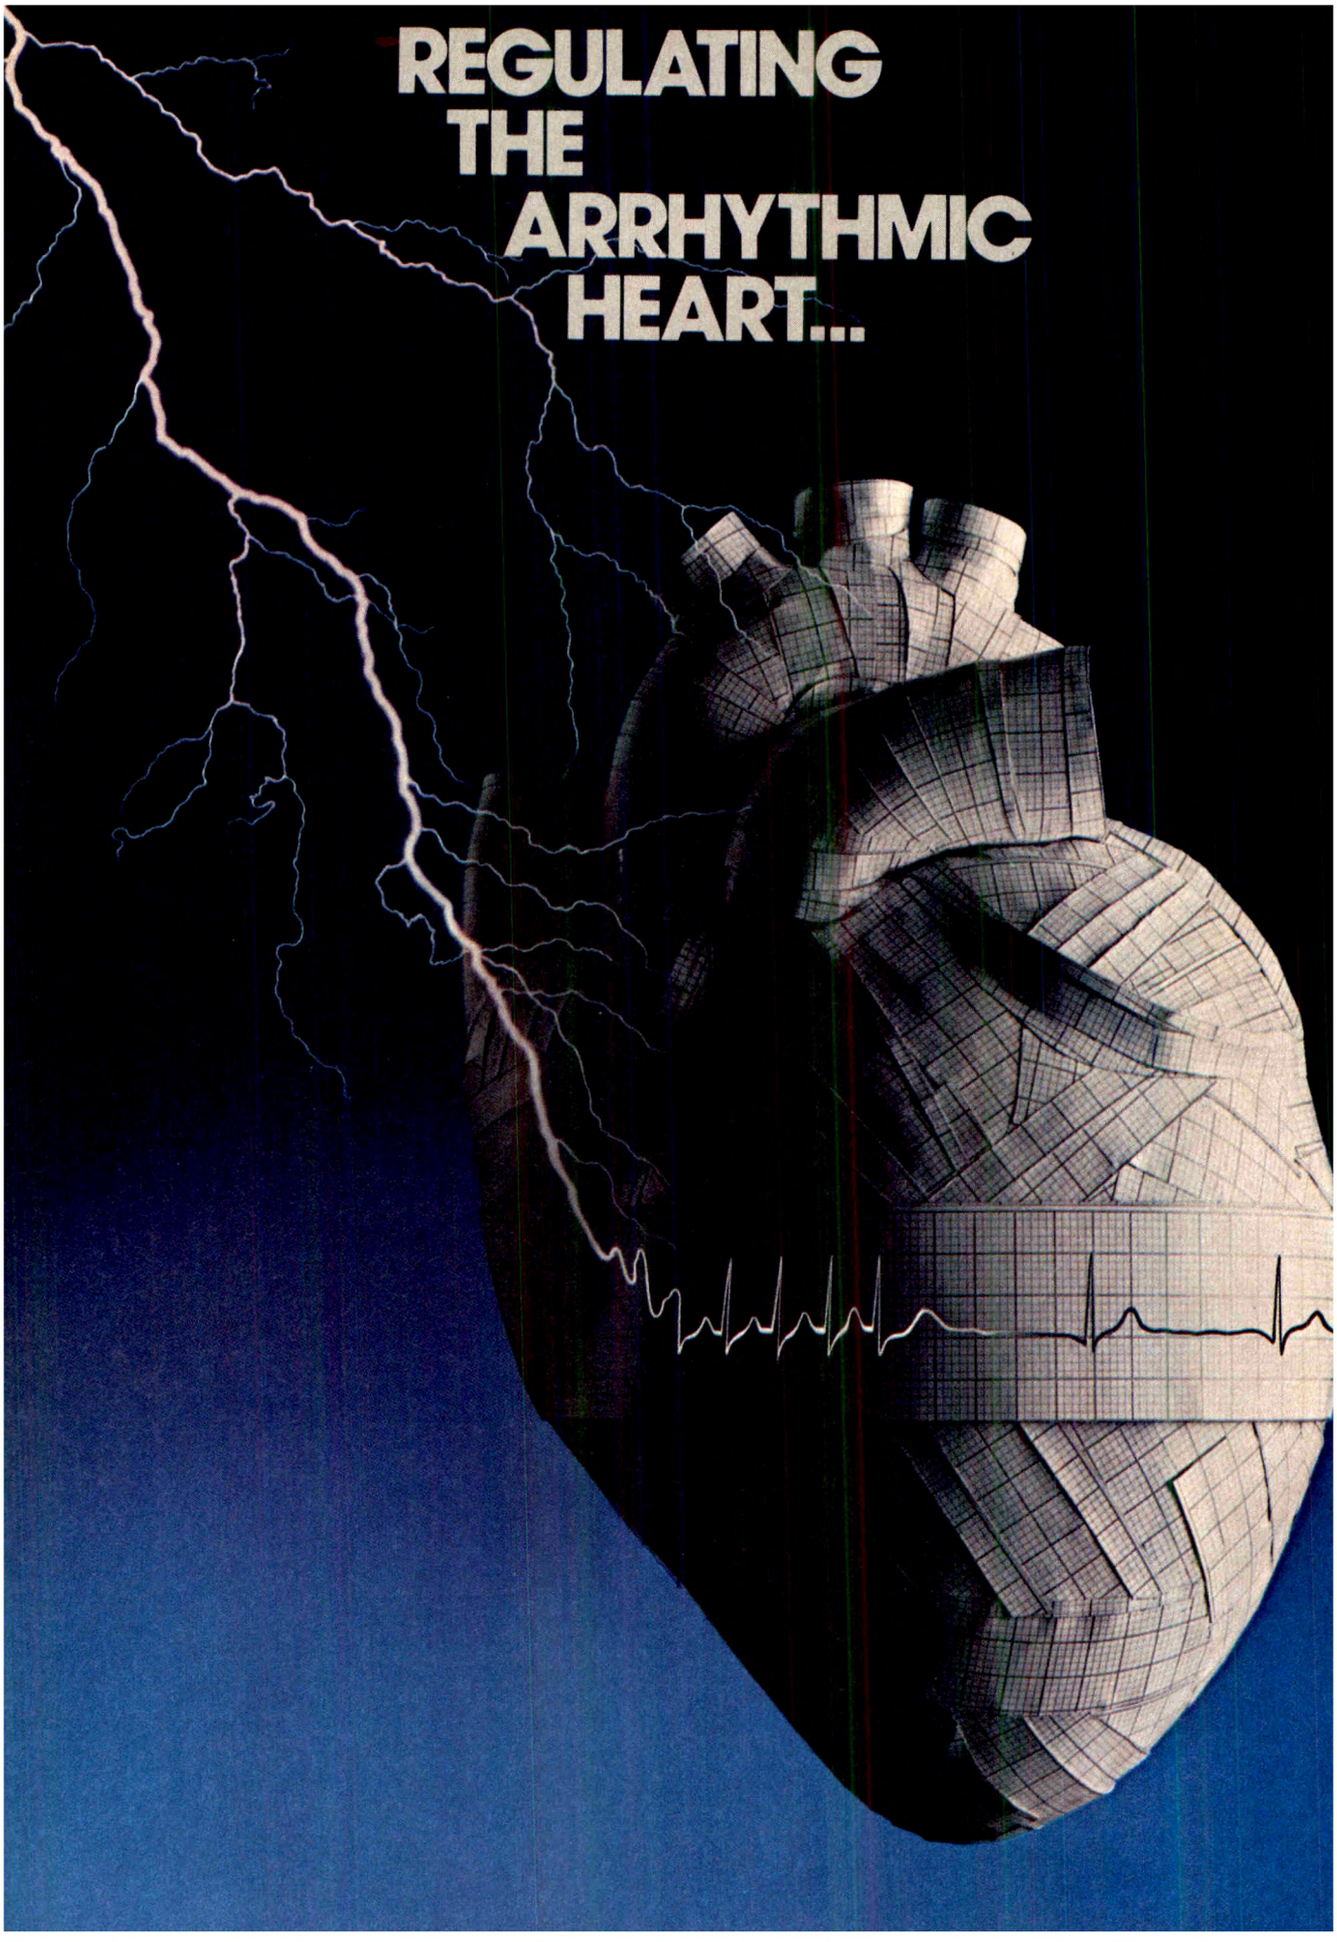
Whole New
Planes of Vision.

Tomovision is a New Dimension in Nuclear Imaging.

Tomovision. As dramatic an advance over current nuclear tomography as tomography was over planar imaging. Large organ and area studies are now possible. And Tomovision gives you clearer images with more detail, fewer artifacts, and better contrast. How does it work? The real secret is in our collimators and programming.

To complement the 7 pinhole collimator, we designed a revolutionary Rotating Slant Hole Collimator. It works on Technicare's small field and large field gamma cameras. And gives you a field of view equal to the diameter of the collimator, beginning at the face of the camera.



So you can see more than ever before. And more clearly than ever before.

So the role of nuclear medicine in research and diagnosis has suddenly expanded. Because tomography is ready to augment the classic diagnostic procedures. Ready to become a routine diagnostic tool.

All Tomovision equipment is manufactured by the Technicare Corporation. So we take care of it all. And we're building our one source reputation with a commitment to excellence. Excellence in training of our field service engineers. Excellence in providing prompt, local service throughout the nation. Tomovision is your assurance that nuclear tomography will deliver consistent, reliable performance for improved clinical confidence.

olongs its refractory time.
owed AV conduction will
ten block reentry circuits, to
lp restore sinus rhythm.

WITH The ECG reads atrial flutter. Or atrial fibrillation. You have digitalized your patient, but the arrhythmia is not yet controlled. Consider adding INDERAL (propranolol HCl). Combined with digitalis, it obviates increasing digitalis dosage to toxic levels—while slowing the ventricular rate sufficiently to achieve control. INDERAL also complements the action of other agents. Combined with quinidine, it allows lower doses of quinidine—reducing the need for toxic levels. And often, with INDERAL added, atrial arrhythmias respond when no single agent works alone.

INSTEAD The arrhythmia is induced by an antiarrhythmic drug such as digitalis or quinidine. Persists after discontinuance of the drug and correction of electrolyte imbalance. Consider INDERAL instead. Often the drug of choice, except in the presence of serious congestive heart failure. Often, too, INDERAL (propranolol HCl) abolishes supraventricular arrhythmias when either digitalis or quinidine has failed.

With proper patient selection—in the absence of contraindications such as bradycardia, greater than first degree heart block, asthma, and congestive heart failure unless failure is secondary to tachyarrhythmias treatable with INDERAL—serious cardiovascular and respiratory side effects are seldom encountered.*
Rely on it: INDERAL. Alone. With. Or Instead.

A PRIME CONSIDERATION FOR SUPRAVENTRICULAR ARRHYTHMIAS

INDERAL®
(PROPRANOLOL HCl)
10mg and 20mg tablets

Ayerst®

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR)
Inderal® BRAND OF propranolol hydrochloride **A beta-adrenergic blocking agent**

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. Propranolol is not significantly dialyzable. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergic blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias.

Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias associated with pheochromocytoma, thyrotoxicosis, exercise).

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATIONS: Cardiac Arrhythmias: *1.) Supraventricular arrhythmias:* a) Paroxysmal atrial tachycardias, particularly those arrhythmias induced by catecholamines or digitalis or associated with the Wolff-Parkinson-White syndrome. (See W-P-W under WARNINGS.) b) Persistent sinus tachycardia which is noncompensatory and impairs the well-being of the patient. c) Tachycardias and arrhythmias due to thyrotoxicosis when causing distress or increased hazard and when immediate effect is necessary as adjunctive, short term (2-4 weeks) therapy. May be used with, but not in place of, specific therapy. (See Thyrotoxicosis under WARNINGS.) d) Persistent atrial extrasystoles which impair the well-being of the patient and do not respond to conventional measures. e) Atrial flutter and fibrillation when ventricular rate cannot be controlled by digitalis alone, or when digitalis is contraindicated.

2.) Ventricular tachycardias: Ventricular arrhythmias do not respond to propranolol as predictably as do the supraventricular arrhythmias. a) Ventricular tachycardias: With the exception of those induced by catecholamines or digitalis, INDERAL is not the drug of first choice. In critical situations when cardioversion technics or other drugs are not indicated or are not effective, INDERAL may be considered. If, after consideration of the risks involved, INDERAL is used, it should be given intravenously in low dosage and very slowly. (See DOSAGE AND ADMINISTRATION.) *Care in the administration of* INDERAL *with constant electrocardiographic monitoring is essential as the failing heart requires some sympathetic drive for maintenance of myocardial tone.* b) Persistent premature ventricular extrasystoles which do not respond to conventional measures and impair the well-being of the patient.

3.) Tachyarrhythmias of digitalis intoxication: If digitalis-induced tachyarrhythmias persist following discontinuance of digitalis and correction of electrolyte abnormalities, they are usually reversible with *oral* INDERAL. Severe bradycardia may occur. (See OVERDOSAGE OR EXAGGERATED RESPONSE.)

Intravenous propranolol hydrochloride is reserved for life-threatening arrhythmias. Temporary maintenance with oral therapy may be indicated. (See DOSAGE AND ADMINISTRATION.)

4.) Resistant tachyarrhythmias due to excessive catecholamine action during anesthesia. Tachyarrhythmias due to excessive catecholamine action during anesthesia may sometimes arise because of release of endogenous catecholamines or administration of catecholamines. When usual measures fail in such arrhythmias, INDERAL may be given intravenously to abolish them. All general inhalation anesthetics produce some degree of myocardial depression. Therefore, when INDERAL is used to treat arrhythmias during anesthesia, it should be used with extreme caution and constant ECG and central venous pressure monitoring. (See WARNINGS.)

Hypertrophic Subaortic Stenosis: INDERAL is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL also improves exercise performance. The effectiveness of INDERAL in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta receptor stimulation. Clinical improvement may be temporary.

Pheochromocytoma: After primary treatment with an alpha-adrenergic blocking agent has been instituted, INDERAL may be useful as *adjunctive* therapy if the control of tachycardia becomes necessary before or during surgery.

It is hazardous to use INDERAL unless alpha-adrenergic blocking drugs are already in use, since this would predispose to serious blood pressure elevation. Blocking only the peripheral dilator (beta) action of epinephrine leaves its constrictor (alpha) action unopposed.

In the event of hemorrhage or shock, there is a disadvantage in having both beta and alpha blockade since the combination prevents the increase in heart rate and peripheral vasoconstriction needed to maintain blood pressure.

With inoperable or metastatic pheochromocytoma, INDERAL may be useful as an adjunct to the management of symptoms due to excessive beta receptor stimulation.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation o angina and, in some cases, myocardial infarction, following *abrupt* discontinuation INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dos should be gradually reduced and the patient carefully monitored. In addition, wher INDERAL is prescribed for angina pectoris, the patient should be cautioned agains interruption or cessation of therapy without the physician's advice. If INDERAL ther is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitut INDERAL therapy and take other measures appropriate for the management of uns ble angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term u not been adequately appraised. Special consideration should be given to propranolol's tial for aggravating congestive heart failure. Propranolol may mask the clinical signs of ing or continuing hyperthyroidism or complications and give a false impression of impro Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of sym of hyperthyroidism, including thyroid storm. This is another reason for withdrawing prop slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have be ported in which, after propranolol, the tachycardia was replaced by a severe bradycard quiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg prop

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release f tenance of adequate cardiac function, beta blockade will impair the desired inotropic e Therefore, INDERAL should be titrated carefully when administered for arrhythmias occ during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of t heart to respond to reflex stimuli. For this reason, with the exception of pheochromocyto INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and siologic effects are gone according to available evidence. However, in case of emergen gery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can b versed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, su tients may be subject to protracted severe hypotension. Difficulty in restarting and main the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONC EMPHYSEMA), INDERAL should be administered with caution since it may block broncl tion produced by endogenous and exogenous catecholamine stimulation of beta recep

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adre blocking activity, INDERAL may prevent the appearance of premonitory signs and symp (pulse rate and pressure changes) of acute hypoglycemia. This is especially important t in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by cipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been es tablished. Use of any drug in pregnancy or women of childbearing potential requires tha possible risk to mother and/or fetus be weighed against the expected therapeutic benef bryotoxic effects have been seen in animal studies at doses about 10 times the maximun ommended human dose.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine s be closely observed if INDERAL is administered. The added catecholamine blocking ac this drug may then produce an excessive reduction of the resting sympathetic nervous a Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be served at regular intervals. The drug should be used with caution in patients with impaire or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensif of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Rayn type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomni tude, weakness, fatigue; reversible mental depression progressing to catatonia; visual d bances; hallucinations; an acute reversible syndrome characterized by disorientation fo and place, short term memory loss, emotional lability, slightly clouded sensorium, and de creased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea stipation, mesenteric arterial thrombosis, ischemic colitis

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with ac and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic pur

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin rous membranes and conjunctivae reported for a beta blocker (practolol) have not been clusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe he ease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DOSAGE AND ADMINISTRATION: The dosage range for INDERAL is different for ea indication.

ORAL

ARRHYTHMIAS—10-30 mg three or four times daily, before meals and at bedtime.

HYPERTROPHIC SUBAORTIC STENOSIS—20-40 mg three or four times daily, before and at bedtime.

PHEOCHROMOCYTOMA—*Preoperatively*—60 mg daily in divided doses for three da to surgery, concomitantly with an alpha-adrenergic blocking agent.—*Management of ino ble tumor*—30 mg daily in divided doses.

PEDIATRIC DOSAGE At this time the data on the use of the drug in this age group are t ited to permit adequate directions for use.

INTRAVENOUS Intravenous administration is reserved for life-threatening arrhythmias those occurring under anesthesia. The usual dose is from 1 to 3 mg administered under c monitoring, *e.g.* electrocardiographic, central venous pressure. The rate of administratior should not exceed 1 mg (1 ml) per minute to diminish the possibility of lowering blood pre and causing cardiac standstill. Sufficient time should be allowed for the drug to reach the action even when a slow circulation is present. If necessary, a second dose may be given two minutes. Thereafter, additional drug should not be given in less than four hours. Addit INDERAL should not be given when the desired alteration in rate and/or rhythm is achiev

Transference to oral therapy should be made as soon as possible.

The intravenous administration of INDERAL has not been evaluated adequately in the agement of hypertensive emergencies.

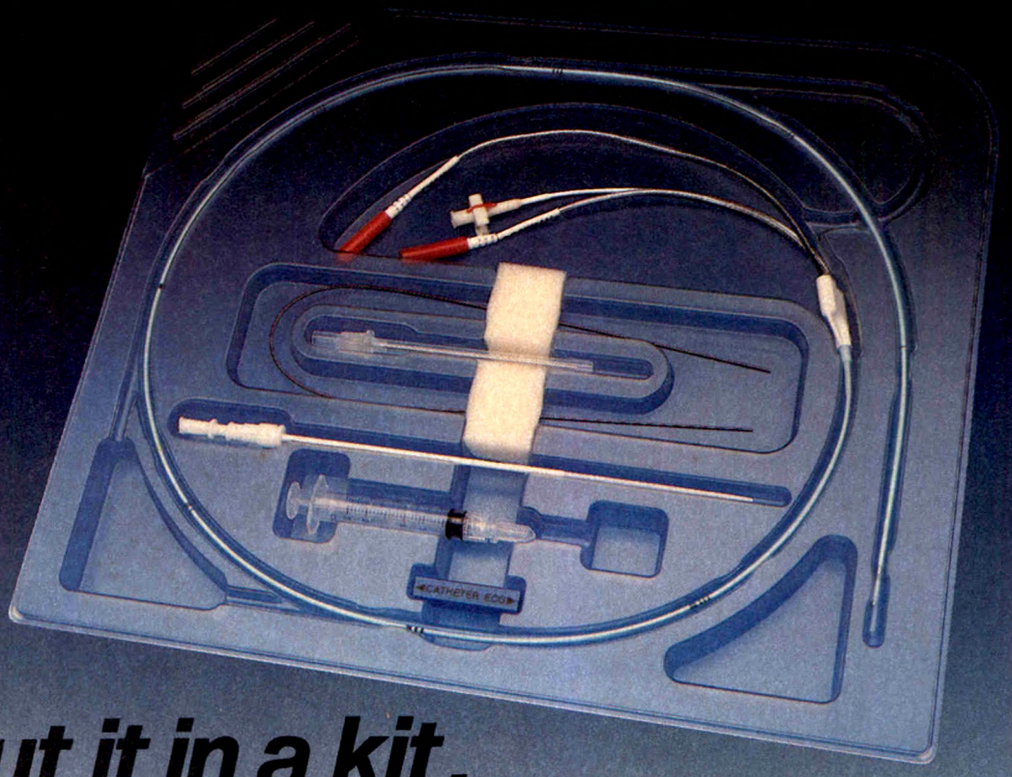
OVERDOSAGE OR EXAGGERATED RESPONSE: IN THE EVENT OF OVERDOSAGE C EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg). IF THERE IS NO RESPON VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS.

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE DENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.



HOW SUPPLIED: INDERAL (propranolol hydrochloride)

TABLETS: *No. 461*—Each scored tablet contains 10 mg of propranolol hydrochloride, in b of 100 and 1,000. Also in unit dose package of 100. *No. 462*—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package 100. *No. 464*—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles 100 and 1,000. Also in unit dose package of 100. *No. 468*—Each scored tablet contains 8(of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE: *No. 3265*—Each ml contains 1 mg of propranolol hydrochloride in Water for tion. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

Ayerst® AYERST LABORATORIES
New York, N.Y. 10017

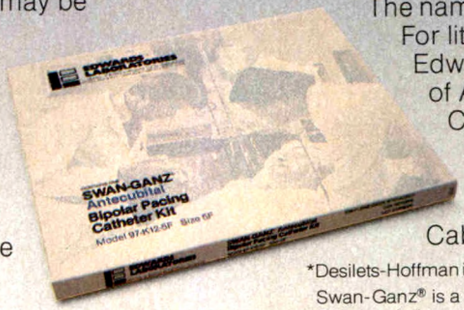
How do you improve on the Swan-Ganz® Pacing Catheter?

Put it in a kit.

The Swan-Ganz Bipolar Pacing Catheter has been shown to provide excellent pacing stability and is well known for its ease of insertion. Now you can get this proven performance with all the convenience of a ready-to-use kit.

A rapid, reliable bedside procedure.

Clinical experience has shown that insertion can be performed at bedside in minutes by using an ECG recording from the distal electrode as a placement guide. Blood flow directs the balloon-tipped catheter rapidly into the right ventricle. No fluoroscopy is needed. Both the catheter body and electrodes are radiopaque and may be visualized by fluoroscopy, if desired.



Quality components for quality pacing.

In addition to the 5-F Swan-Ganz Bipolar Pacing Catheter, the kit contains the basic components needed for prompt, reliable catheter placement: a Desilets-Hoffman* type percutaneous insertion set for maximum ease in insertion, a unique syringe designed to ensure proper balloon inflation and a convenient ECG adapter.

Two types of kits are available. One is designed for antecubital, subclavian or internal jugular vein insertion. The other, for femoral insertion, has a "J" shaped tip to facilitate entry from the inferior vena cava. Either may be used with most external pacemakers.

So now get reliable emergency pacing and ease of insertion with all the convenience of a ready-to-use kit.

The Swan-Ganz Bipolar Pacing Catheter Kit. The name to rely on for quality pacing.

American Edwards Laboratories

Fruitless?

A Question of Compliance.

Patients on potassium supplements *won't* comply if they tire of the sweet fruity taste used to mask the "bitter pill" of potassium in their medication.

That's when a prescription for the fruitless taste of KATO potassium supplement can be fruitful.

KATO Supplement. The compatible taste of tomato.

In KATO supplement, the naturally tangy taste of tomato *complements* the naturally salty taste of potassium chloride. Patients like the combination, and will stay with it day after day. Tomato-flavored KATO supplement is a natural — at breakfast and dinner.

KATO Supplement. The preferred salt in the preferred form.

Each single-dose packet of KATO supplement contains 20 mEq of potassium chloride — the preferred salt — and less than 5 mg sodium chloride. Because it contains the chloride salt, KATO supplement can be used where hypochloremic alkalosis is also a problem. KATO supplement mixes easily in water or tomato juice, and just two packets daily provide a full therapeutic dose.

Fruitful.

KATO Supplement.
It's fruitless for fruitful compliance.

- tangy, tomato taste well accepted for long-term compliance
- B.I.D. regimen encourages compliance
- liquid form minimizes potential for gastrointestinal irritation
- corrects both hypokalemia and hypochloremic alkalosis
- convenient, easy-to-carry single-dose packets

KATO®
(potassium chloride
for oral solution) 20 mEq
(1.5 g KCl)

SYNTEX

SYNTEX PUERTO RICO, INC.
HUMACAO, PUERTO RICO 00661

Please see prescribing information on following page.

KATO®
(potassium chloride for oral solution)

20 mEq (1.5 g KCl)

Prescribing Information

DESCRIPTION:
Spray-dried tomato powder containing 20 mEq potassium (equivalent to 1.5 g KCl) per 6 grams powder (one dose) with natural and synthetic flavors, spices and colors. Benzoic acid and potassium benzoate added as preservatives. When reconstituted as directed, makes a pleasantly flavored, low sodium tomato juice drink. Each daily dose (2 packets) contains approximately 0.5 mEq sodium.

INDICATIONS:
The prevention or correction of potassium deficit, particularly when accompanied by hypochloremic alkalosis in conjunction with thiazide diuretic therapy, in digitalis intoxication, or as the result of long-term corticosteroid therapy, low dietary intake of potassium, or excessive vomiting or diarrhea.

CONTRAINDICATIONS:
Potassium is contraindicated in severe renal impairment involving oliguria, anuria or azotemia; in untreated Addison's disease, familial periodic paralysis, acute dehydration, heat cramps, hyperkalemia from any cause. Potassium chloride should not be employed in patients receiving potassium-sparing agents such as aldosterone antagonists and triamterene.

PRECAUTIONS:
KATO is a concentrate and should be taken only after reconstituting with water as directed. This preparation, like other potassium supplements, must be properly diluted to avoid the possibility of gastrointestinal irritation. Do not use in patients with low urinary output or renal decompensation. Administer with caution; it is impossible to assess accurately the daily dose required. Excessive dosage may result in potassium intoxication. Frequent checks of the clinical status of the patient, ECG and/or plasma potassium level should be made. High plasma concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease.

ADVERSE REACTIONS:
Vomiting, diarrhea, nausea, and abdominal discomfort may occur. Gross overdosage may produce signs and symptoms of potassium intoxication: mental confusion, listlessness, paresthesia of the extremities, weakness and heaviness of legs, flaccid paralysis, hyperkalemia, ECG abnormalities, fall in blood pressure, cardiac arrhythmias and heart block. The characteristic changes in the ECG are disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, tall peaked T waves, etc.

TOXICITY:
Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

TREATMENT OF HYPERKALEMIA:
1. Dextrose solution 10% or 25% containing 10 units of crystalline insulin per 20 g dextrose, given I.V. in a dose of 300cc to 500cc in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally or as retention enema. 3. Hemodialysis or peritoneal dialysis. 4. Elimination of potassium-containing foods and medicaments. Warning: Digitalis toxicity can be precipitated by lowering the plasma potassium concentration too rapidly in digitalized patients.

ADMINISTRATION AND DOSAGE:
Mix with water to make a pleasant tomato juice drink. Each 6-gram unit dose packet provides 20 mEq of potassium. Usual adult dose—1 packet of KATO mixed with about 2 ounces of water twice daily—supplies 40 mEq potassium per day. Take with meals or follow with ½ glass of water. Larger doses may be required, but should be administered under close supervision because of the possibility of potassium intoxication.

HOW SUPPLIED:
Cartons of 30 and 120 6-gram unit dose packets, 20 mEq each.

CAUTION:
Federal law prohibits dispensing without a prescription.

When exact measurement of home exercise programs is essential.....

The Amerec Tunturi Ergometer

With the Amerec Tunturi, physician, therapist and patient all know exactly how much exercise is being performed. Progressive rehabilitation programs can be monitored and adjusted with confidence. The brake scale accurately registers the amount of energy expended in watts—at both 50 and 60 revolutions per minute. Tension adjustment is infinitely variable. Disc brakes apply quiet, even resistance. And the easy-to-read tachometer/odometer registers revolutions per minute and total distance pedalled.

The Amerec Tunturi is as convenient as it is accurate. The flywheel acts as a caster to roll where needed. An effective exercise program requires less than a square yard of floor space.

Learn about the other features of this advanced, Finnish-built ergometer. We'll forward complete details at your request. Write Amerec, Box 3825, Bellevue, Washington 98009. (800) 426-0858.

Antiarrhythmia Bulletin No. 2

Quinidine Withdrawal or Replacement May Decrease Physiologic Effect of Digoxin

Some Further Reports on Problems Arising From the Quinidine-Digoxin Interaction

"An increase in serum digoxin concentration after quinidine is added is now anticipated by many physicians. The opposite is predictable from this observation: a fall in the serum concentration and physiologic effect of digoxin when quinidine is withdrawn from a patient previously stable on both drugs. Although an example of this fall has been reported, little emphasis has been given to this aspect of the quinidine-digoxin interaction, which may have important consequences....

"It appears that this [a 62-year-old female] patient's symptoms and increase in ventricular rate were due to a decrease in serum digoxin concentration and physiologic effect caused by withdrawal of quinidine. This phenomenon should be anticipated when quinidine is discontinued or replaced by other antiarrhythmic therapy in patients previously stable on digoxin and quinidine, especially those in atrial fibrillation, and may require an appropriate readjustment of digoxin dosage based on clinical observations and measured serum digoxin concentrations."

—From Moench, T.R.: The Quinidine-Digoxin Interaction, N. Engl. J. Med. *302*:864, 1980.

"Dr. Moench reports a case that supports the view that quinidine withdrawal can decrease the effect of digoxin. The end point in his study was the time-honored ventricular response to atrial fibrillation, i.e., atrioventricular nodal conduction. His case report provides another bit of evidence that the change in serum digoxin concentration during the interaction often reflects the effect of digoxin on the heart. This hypothesis is difficult to test, and the observations of Dr. Moench are helpful in view of the increasingly complex picture of the interaction."

—From Bigger, J.T., Jr.: The Quinidine-Digoxin Interaction, N. Engl. J. Med. *302*:864–865, 1980.

Do Other Antiarrhythmics Interact With Digoxin?

"We compared the effects of quinidine and three alternate antiarrhythmic drugs on serum digoxin concentration in 63 patients before and during administration of quinidine, procainamide, disopyramide, or mexiletine. Quinidine increased digoxin concentration by at least 0.5 nmol/L in 21 of 22 patients: Mean serum digoxin rose from 1.2 nmol/L to 2.4 nmol/L ($P<0.001$). Procainamide, disopyramide, or mexiletine increased serum digoxin by 0.5 nmol/L in one of 41 patients. Anorexia, nausea, and vomiting developed soon after starting quinidine therapy in 10 of the 22 patients who received quinidine but in only five of the 41 patients who received procainamide, disopyramide, or mexiletine ($P<0.01$). Quinidine prolonged the PR interval from 160 ± 14 ms to 183 ± 26 ms, but procainamide, disopyramide, and mexiletine did not change the PR interval ($P < 0.005$). In digitalized patients, quinidine increases serum digoxin concentration, increases digoxin's effect on atrioventricular conduction, and produces more adverse gastrointestinal effects than procainamide, disopyramide, or mexiletine....

"Figure 1 shows the change in serum digoxin concentrations during administration of the four antiarrhythmic drugs. Each dot represents, for one patient, the difference between the mean serum digoxin concentration before and during therapy with quinidine, procainamide, disopyramide, or mexiletine....

"Because interaction between digoxin and quinidine is common and because quinidine's potential for producing toxicity is still unknown, we recommend that caution be exercised when quinidine is given to digitalized patients....

"Our study shows that several other orally active antiarrhythmic drugs fail to cause an increase in serum digoxin concentration."

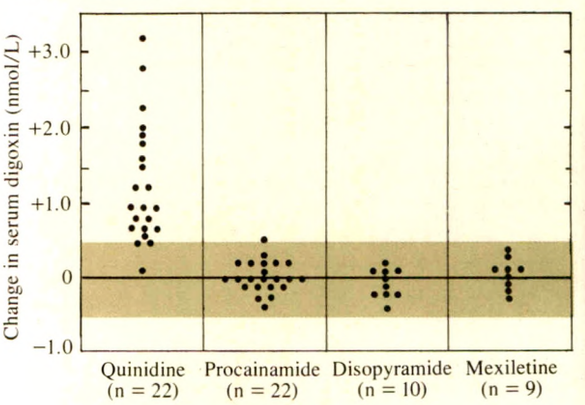

Figure 1.

—From Leahey, E.B., Jr., and others: The Effect of Quinidine and Other Oral Antiarrhythmic Drugs on Serum Digoxin: A Prospective Study, Ann. Intern. Med. *92*:605–608, 1980.

From what has appeared in the literature concerning the elevation of digoxin levels with concomitant quinidine use and reported lack of elevation of digoxin levels with concomitant Norpace® (disopyramide phosphate) use, it would appear that Norpace could be a logical alternative to quinidine in some patients using digoxin concomitantly.

Please see the next page for complete prescribing information

NORPACE® CAPSULES (disopyramide phosphate)

DESCRIPTION

Norpace (disopyramide phosphate) is an antiarrhythmic drug available for oral administration in capsules containing 100 mg or 150 mg of disopyramide base, present as the phosphate. The base content of the phosphate salt is 77.6%.

The structural formula of Norpace is seen at the right. Norpace is freely soluble in water, and the free base (pKa 8.36) has an aqueous solubility of 1 mg/ml. The chloroform: water partition coefficient of the base is 3.1 at pH 7.2. Norpace is a racemic mixture of *d*- and *l*-isomers. This drug is not chemically related to other antiarrhythmic drugs.

α-[2-(diisopropylamino) ethyl]-α-phenyl-2-pyridineacetamide phosphate

CLINICAL PHARMACOLOGY

Mechanisms of action: Norpace (disopyramide phosphate) is a Type 1 antiarrhythmic drug (i.e., similar to procainamide and quinidine). *In animal studies* Norpace decreases the rate of diastolic depolarization (phase 4) in cells with augmented automaticity, decreases the upstroke velocity (phase 0) and increases the action potential duration of normal cardiac cells, decreases the disparity in refractoriness between infarcted and adjacent normally perfused myocardium and has no effect on alpha- or beta-adrenergic receptors.

Electrophysiology: In man, Norpace at therapeutic plasma levels shortens the sinus node recovery time, lengthens the effective refractory period of the atrium and has a minimal effect on the effective refractory period of the AV node. Little effect has been shown on AV-nodal and His-Purkinje conduction times or QRS duration. However, prolongation of conduction in accessory pathways occurs.

Hemodynamics: At recommended oral doses, Norpace rarely produces significant alterations of blood pressure in patients without congestive heart failure (see *Warnings*). Intravenous injection (2 mg/kg over 3 minutes) produces a moderate, transient increase in heart rate and in total peripheral resistance. In patients with organic heart disease intravenous Norpace causes cardiac depression, with approximately a 10% reduction of cardiac output.

Anticholinergic activity: The *in vitro* anticholinergic activity of Norpace is approximately 0.06% that of atropine; however, the usual dose of Norpace is 150 mg every 6 hours compared to 0.4-0.6 mg for atropine (see *Warnings* and *Adverse Reactions* for anticholinergic side effects).

Pharmacokinetics: Following oral administration disopyramide phosphate is rapidly and almost completely absorbed, and peak plasma levels are usually attained within two hours. The usual therapeutic plasma levels of disopyramide *free base* are 2-4 mcg/ml and at these concentrations protein binding varies from 50-65%. Because of concentration-dependent protein binding, it is difficult to predict the concentration of the free drug when total drug is measured.

The mean plasma half-life of disopyramide in healthy humans is 6.7 hours (range of 4 to 10 hours). In six patients with impaired renal function (creatinine clearance less than 40 ml/min), disopyramide half-life values were 8 to 18 hours.

In healthy men about 50% of a given dose of disopyramide is excreted in the urine as the unchanged drug, about 20% as the mono-N-dealkylated metabolite and 10% as the other metabolites. The plasma concentration of the major metabolite is approximately one tenth that of disopyramide. Altering the urinary pH in man does not affect the plasma half-life of disopyramide.

INDICATIONS

Norpace should be prescribed only after appropriate electrocardiographic assessment.

Norpace (disopyramide phosphate) is indicated for suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination:

1. Unifocal premature (ectopic) ventricular contractions.
2. Premature (ectopic) ventricular contractions of multifocal origin.
3. Paired premature ventricular contractions (couplets).
4. Episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion).

In controlled trials of ambulatory patients Norpace was as effective as 325 mg quinidine q 6 h in reducing the frequency of ventricular ectopic activity. Norpace was equally effective in digitalized and nondigitalized patients. Norpace is also equally effective in the treatment of primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease.

Oral Norpace (disopyramide phosphate) has not been adequately studied in patients with acute myocardial infarction or in patients with persistent ventricular tachycardia or atrial arrhythmias.

Type 1 antiarrhythmic drugs are usually not effective in treating arrhythmias secondary to digitalis intoxication and, therefore, Norpace is not indicated for such cases.

The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.

CONTRAINDICATIONS

Norpace (disopyramide phosphate) is contraindicated in the presence of cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.

WARNINGS

Negative inotropic properties: Heart failure/hypotension: **Norpace may cause or worsen congestive heart failure or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily in patients with primary cardiomyopathy or inadequately compensated congestive heart failure. Norpace should not be used in patients with uncompensated or marginally compensated congestive heart failure or hypotension unless the congestive heart failure or hypotension is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace, but careful attention must be given to the maintenance of cardiac function, including optimal digitalization. If hypotension occurs or congestive heart failure worsens, Norpace should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established.**

QRS widening: **Although it is unusual, significant widening (greater than 25%) of the QRS complex may occur during Norpace administration; in such cases Norpace (disopyramide phosphate) should be discontinued.**

Q-T prolongation: **As with other Type 1 antiarrhythmic drugs, prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If a Q-T prolongation of greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and consideration be given to discontinuing Norpace (disopyramide phosphate).**

Hypoglycemia: **In rare instances significant lowering of blood glucose values has been reported during Norpace administration.** The physician should be alert to this possibility, especially in patients with congestive heart failure, chronic malnutrition, hepatic, renal or other diseases or drugs (e.g., beta adrenoceptor blockers, alcohol) which could compromise preservation of the normal glucoregulatory mechanisms in the absence of food. In these patients the blood glucose levels should be carefully followed.

Concomitant antiarrhythmic therapy: **The concomitant use of Norpace with other Type 1 antiarrhythmic agents (such as quinidine or procainamide) and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction.** This should be considered particularly in patients with any degree of cardiac decompensation or those with a prior history thereof. Patients receiving more than one antiarrhythmic drug must be carefully monitored.

Heart block: **If first-degree heart block develops in a patient receiving Norpace, the dosage should be reduced.** If the block persists despite reduction of dosage, continuation of the drug must depend upon weighing the benefit being obtained against the risk of higher degrees of heart block. Development of second- or third-degree AV block or unifascicular, bifascicular or trifascicular block requires discontinuation of Norpace therapy, unless the ventricular rate is adequately controlled by a temporary or implanted ventricular pacemaker.

Anticholinergic activity: **Because of its anticholinergic activity, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention unless adequate overriding measures are taken;** these consist of the topical application of potent miotics (e.g., pilocarpine) for patients with glaucoma, and catheter drainage or operative relief for patients with urinary retention. Urinary retention may occur in patients of either sex as a consequence of Norpace administration, but males with benign prostatic hypertrophy are at particular risk. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace therapy. Norpace should be used with special care in patients with myasthenia gravis since its anticholinergic properties could precipitate a myasthenic crisis in such patients.

PRECAUTIONS

Atrial tachyarrhythmias: Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not result in an increase of ventricular rate beyond physiologically acceptable limits.

Conduction abnormalities: Care should be taken when prescribing Norpace for patients with sick sinus syndrome (bradycardia-tachycardia syndrome), Wolff-Parkinson-White syndrome (WPW), or bundle branch block. The effect of Norpace (disopyramide phosphate) in these conditions is uncertain at present.

Cardiomyopathy: Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace, probably due to cardiodepressant mechanisms. Therefore, a loading dose of Norpace should not be given to such patients and initial dosage and subsequent dosage adjustments should be made under close supervision (see *Dosage and Administration*).

Drug interactions: Other antiarrhythmic drugs (e.g., quinidine, procainamide, lidocaine, propranolol) have occasionally been used concurrently with Norpace but no specific drug interaction studies have been conducted (see *Warnings*). Excessive widening of the QRS complex and/or prolongation of the Q-T interval may occur in these situations. Norpace does not increase serum digoxin levels.

Renal impairment: More than 50% of disopyramide is excreted in the urine unchanged. Therefore Norpace dosage should be reduced in patients with impaired renal function (see *Dosage and Administration*). The electrocardiogram should be carefully monitored for prolongation of PR interval, evidence of QRS widening or other signs of overdosage (see *Overdosage*).

Hepatic impairment: Hepatic impairment also causes an increase in the plasma half-life of disopyramide. Dosage should be reduced for patients with such impairment. The electrocardiogram should be carefully monitored for signs of overdosage (see *Overdosage*).

Hypokalemia: Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace (disopyramide phosphate) therapy.

Pregnancy: Reproduction studies in rats and teratology studies performed both in rats and in rabbits have revealed minimal evidence of impaired fertility. No fetal anomalies were attributable to Norpace. Disopyramide has been found in human fetal blood. However, well-controlled studies of Norpace have not been performed in pregnant women and experience with Norpace during pregnancy is limited; therefore the possibility of damage to the fetus cannot be excluded.

Norpace has been reported to stimulate contractions of the pregnant uterus. Norpace (disopyramide phosphate) should be used in pregnant women only when it is clearly indicated and the benefit/risk ratio has been carefully evaluated.

Labor and delivery: It is not known whether the use of Norpace during labor or delivery has immediate or delayed adverse effects on the fetus, or whether it prolongs the duration of labor or increases the need for forceps delivery or other obstetric intervention.

Nursing mothers: Studies in rats have shown that the concentration of disopyramide and its metabolite is between one and three times greater in milk than it is in plasma. Following oral administration, disopyramide has been detected in human milk at a concentration not exceeding that in plasma. Therefore, if use of the drug is deemed essential, an alternative method of infant feeding should be instituted.

Pediatrics: The safety and effectiveness of Norpace in children have not been established.

ADVERSE REACTIONS

The adverse reactions which were reported in clinical trials encompass observations in 1,500 patients, including 90 patients studied for at least four years. The most serious adverse reactions are hypotension and congestive heart failure. The most common adverse reactions, which are dose dependent, are associated with the anticholinergic properties of the drug. These may be transitory, but may be persistent or can be severe. Urinary retention is the most serious anticholinergic effect.

The following reactions were reported in 10-40% of patients:

Anticholinergic: dry mouth (32%), urinary hesitancy (14%), constipation (11%)

The following reactions were reported in 3-9% of patients:

Anticholinergic: blurred vision, dry nose/eyes/throat
Genitourinary: urinary frequency and urgency
Gastrointestinal: nausea, pain/bloating/gas
General: dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains

The following reactions were reported in 1-3% of patients:

Anticholinergic: urinary retention
Genitourinary: impotence
Cardiovascular: hypotension with or without congestive heart failure, increased congestive heart failure (see *Warnings*), cardiac conduction disturbances (see *Warnings*), edema/weight gain, shortness of breath, syncope, chest pain
Gastrointestinal: anorexia, diarrhea, vomiting
Dermatologic: generalized rash/dermatoses, itching
Central nervous system: nervousness
Other: hypokalemia, elevated cholesterol/triglycerides

The following reactions were reported in less than 1%:

Depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit

Hypoglycemia has been reported in association with Norpace (disopyramide phosphate) administration (see *Warnings*).

Rarely, acute psychosis has been reported following Norpace therapy, with prompt return to normal mental status when therapy was stopped. Infrequent occurrences of reversible cholestatic jaundice have been reported in association with disopyramide therapy as have rare instances of reversible agranulocytosis. The physician should be aware of these possible reactions and should discontinue Norpace therapy promptly if they occur.

DOSAGE AND ADMINISTRATION

The dosage of Norpace (disopyramide phosphate) must be individualized for each patient on the basis of response and tolerance. The usual adult dosage of Norpace is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients whose body weight is less than 110 pounds (50 kg), the recommended dosage is 100 mg every six hours.

For patients with cardiomyopathy or possible cardiac decompensation, a loading dose, as discussed below, should not be given and initial dosage should be limited to 100 mg of Norpace every six hours. Subsequent dosage adjustments should be made gradually, with close monitoring for the possible development of hypotension and/or congestive heart failure (see *Warnings*).

For patients with moderate renal insufficiency (creatinine clearance greater than 40 ml/min) or hepatic insufficiency, Norpace dosage of 100 mg every six hours is recommended, with or without an initial loading dose of 200 mg.

For patients with severe renal insufficiency (C_{Cr} less than 40 ml/min) the recommended dosage regimen is an initial loading dose of 150 mg followed by a maintenance dose of 100 mg at intervals shown in the table below:

NORPACE DOSAGE INTERVAL FOR PATIENTS WITH RENAL INSUFFICIENCY

Creatinine clearance (ml/min)	40-30	30-15	less than 15
Approximate maintenance-dosing interval	q 8 hr	q 12 hr	q 24 hr

For patients in whom rapid control of ventricular arrhythmia is essential, an initial loading dose of 300 mg Norpace (200 mg for patients whose body weight is less than 110 pounds) is recommended, followed by appropriate maintenance dosage. Therapeutic effects are usually attained 30 minutes to three hours after administration of a 300-mg loading dose. If there is no response nor evidence of toxicity within six hours the loading dose, 200 mg every six hours may be prescribed instead of the usual 150 mg. If there is no response to this dosage within 48 hours, either Norpace should then be discontinued or the physician should consider hospitalizing the patient for careful monitoring while subsequent doses of 250 or 300 mg every six hours are given. A limited number of patients with severe refractory ventricular tachycardia have tolerated daily doses of Norpace up to 1600 mg per day (400 mg every 6 hours) resulting in disopyramide plasma levels up to 9 mcg/ml. If such treatment is warranted, it is essential that patients be hospitalized for close evaluation and continuous monitoring.

Transferring to Norpace: The following dosage schedule based on theoretical considerations rather than experimental data is suggested for transferring patients with normal renal function from either quinidine sulfate or procainamide therapy (Type 1 antiarrhythmic agents) to Norpace therapy.

Norpace may be started using the regular maintenance schedule **without a loading dose** 6-12 hours after the last dose of quinidine sulfate or 3-6 hours after the last dose of procainamide.

In patients where withdrawal of quinidine sulfate or procainamide is likely to produce life-threatening arrhythmias, the physician should consider hospitalization of the patient.

OVERDOSAGE

No specific antidote for Norpace has been identified. Treatment of overdosage should be supportive and may include the administration of isoproterenol, dopamine, hemoperfusion with charcoal, hemodialysis, intra-aortic balloon counterpulsation and mechanically assisted respiration.

In vitro studies with human blood have demonstrated good dialyzability for disopyramide. Its clearance was 33 ml/min at a blood flow of 250 ml/min when an initial plasma concentration of 22 mcg/ml was dialyzed using an artificial kidney (Cordis-DOW-4).

On the basis of animal studies toxic plasma levels of disopyramide might be expected to produce excessive widening of the QRS complex and Q-T interval, worsening of congestive heart failure, hypotension, various kinds and degrees of conduction disturbance, bradycardia and finally asystole. Obvious anticholinergic effects might also be observed. The electrocardiogram should be monitored and supportive therapy with vasopressors, sympathomimetics, cardiac glycosides and diuretics should be given as required.

HOW SUPPLIED

Norpace (disopyramide phosphate) is supplied in hard gelatin capsules containing either 100 mg or 150 mg of disopyramide base.

Norpace 100-mg capsules are white and orange, with markings SEARLE and 2752. Norpace 150-mg capsules are brown and orange, with markings SEARLE and 2762.

Available in bottles of 100, 500, and 1,000 capsules, and cartons of 100 unit-dose individually blister-sealed capsules.

Continuous Fractionated Electrical Activity After Stimulation of the Ventricles During the Vulnerable Period: Evidence for Local Reentry

DAVID E. EULER, PhD*
E. NEIL MOORE, DVM, PhD, FACC

Philadelphia, Pennsylvania

Ventricular multiple extrasystoles and fibrillation were induced in open chest dogs by the delivery of either a single electrical pulse or a train of pulses to the right ventricle during the vulnerable period of the cardiac cycle. Bipolar epicardial electrodes delivered current while bipolar plunge electrodes recorded the activation complexes at various distances from the stimulation site. At stimulus intensities below the threshold for multiple ventricular responses, the electrograms recorded from muscle adjacent to the stimulation site showed fragmented activation complexes that lasted considerably longer than the control complexes. At stimulus intensities that evoked multiple ventricular extrasystoles or fibrillation, the fragmented electrical activity became continuous and bridged the diastolic interval between successive ectopic complexes. The continuous fractionated electrical activity that preceded the appearance of multiple extrasystoles and fibrillation was recorded only from electrodes placed within a few millimeters of the stimulating electrodes and could be evoked only by stimulation during the vulnerable period. Disappearance of the fractionated local electrical activity during a run of extrasystoles was followed immediately by the resumption of a normal rhythm. In addition, the fractionated continuous electrical activity that appeared after delivery of a single stimulus during the vulnerable period could be abolished by the delivery of a second stimulus during the protective zone. The presence of continuous local electrical activity before the development of multiple extrasystoles and fibrillation provides strong evidence that the ventricular fibrillation threshold technique operates by producing local reentrant activity.

The experiments of Wiggers and Wegria[1] in 1940 first demonstrated that an appropriately timed electrical stimulus of sufficient energy delivered to the ventricles in late systole could result in ventricular fibrillation. These investigators[2] later defined the "ventricular fibrillation threshold" as the current strength of a brief direct current shock of constant duration (0.01–0.03 s) that is just able to induce fibrillation when applied during the vulnerable period of late systole. To minimize the amount of time required to locate the vulnerable period precisely, Han[3] introduced a technique for measuring vulnerability to fibrillation in which a train of constant current pulses scanned the T wave of the electrocardiogram. Although many studies have used electrical stimulation of the ventricles to assess vulnerability to fibrillation, the mechanism by which current delivered during the vulnerable period initiates fibrillation remains unknown. Moe et al.[4] demonstrated that ventricular fibrillation induced by a single stimulus delivered during the vulnerable period began with a series of multiple extrasystoles originating from the vicinity of the stimulating electrodes. By mapping the spread of activation of the initial extrasystoles with bipolar electrograms they eliminated the possibility of a macroreentrant circuit and suggested that the initial

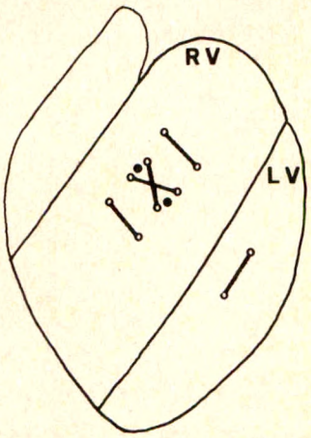

FIGURE 1. Schematic diagram of the heart indicating the placement of stimulating and recording electrodes. **Solid circles** indicate the position of the bipolar electrodes used to deliver current during the vulnerable period (interelectrode distance 7 mm). **Open circles** indicate the position of the bipolar recording electrodes on the right (RV) and left (LV) ventricles. The two recording electrodes in each pair were separated by a distance of 5 to 7 mm.

impulses originated from an automatic center created by the stimulus current. However, because the direct bipolar recordings made by Moe et al.[4] were never closer than 6 mm from the stimulating electrodes, they were unable to eliminate the possibility of local reentry.

Recent studies in both human subjects[5] and experimental animals[6,7] have suggested that local reentry can be identified in bipolar electrograms as the presence of continuous electrical activity bridging the diastolic interval between consecutive ectopic complexes. Thus, the purpose of the present experiments was to use multiple bipolar electrograms to locate areas of continuous electrical activity that precede the development of multiple extrasystoles and fibrillation when current is applied to the myocardium during the vulnerable period.

Methods

Experimental preparation: Experiments were performe in 12 adult mongrel dogs weighing 13 to 20 kg. The dogs wer anesthetized with sodium pentobarbital (30 mg/kg bod weight intravenously) and ventilated with room air with us of a positive pressure respirator (Harvard 607). A left thora cotomy was performed in the fourth and fifth intercosta spaces and the fifth rib removed. The stellate ganglia wer decentralized bilaterally to slow the spontaneous heart rat and intramural bipolar electrodes were applied to the lef atrium to pace the heart at a constant basic cycle length of 40 to 500 ms. A small thermistor probe (YSI 427) was sutured t the left ventricular epicardium and temperature was main tained constant at 37 to 38° C with use of a heating lamp. femoral artery was cannulated and arterial blood pressur monitored continuously throughout the experiment.

Electrophysiologic protocol: Ventricular arrhythmia were induced by passing either a single square wave impuls (10 ms) or a gated train of impulses (14 pulses, 4 ms, 100 hertz through bipolar electrodes during the vulnerable period of th T wave of the electrocardiogram. The stimulating electrode consisted of two 21 gauge stainless steel hypodermic needle embedded in an acrylic plaque. The two needles were sepa rated by 7 mm and extended 2 mm from the surface of th plaque. The trains or single stimuli were synchronized to th atrial stimulus and were delivered after every 15th ventricula response. The single stimuli were delivered to the myocardium beginning in the absolute refractory period and were move by 5 ms increments through the relative refractory period t permit location of the most vulnerable portion of the cardia cycle. In addition to delivery of single pulses during the vul nerable period, in several experiments an additional stimulu was introduced 30 to 50 ms after the initial stimulus in orde to engage the protective zone. When trains of stimuli were delivered during the vulnerable period they were timed t start during the S-T segment of the electrocardiogram and t terminate 20 ms beyond the T wave. The current intensity o all stimuli was measured directly by recording the voltag reduction across a precision 100 ohm resistor in series with th electrodes. When fibrillation occurred in response to either a train of stimuli or a single stimulus, defibrillation wa achieved within 15 seconds with direct current counter shock.

The recording electrodes consisted of Teflon®-coated stainless steel wires (diameter 0.007 inch [0.178 cm]) threaded

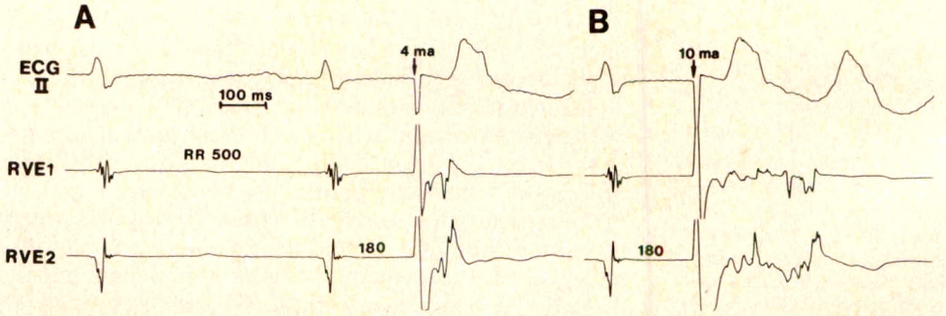

FIGURE 2. The effect of stimulus intensity on the appearance of fractionated electrical activity. Two bipolar electrograms from the right ventricle (RVE1 and RVE2) are shown with a lead II electrocardiogram (ECG). The bipolar electrograms were recorded from electrodes contiguous to the stimulating electrodes (Fig. 1). The atria were driven at a basic cycle length of 500 ms. **A,** after a control cycle, a 4 mA stimulus is delivered to the right ventricle 180 ms after the intrinsic deflection of the basic response in RVE2. A single premature systole appears in the electrocardiogram; both bipolar electrograms show fractionated electrical activity lasting 110 ms beyond the onset of the stimulus artifact. **B,** the stimulus strength is increased to 10 mA, resulting in two premature ventricular complexes. Both bipolar electrograms show fractionated electrical activity that spans the interval in the electrocardiogram between the two premature complexes.

through a 25 gauge hypodermic needle and bent at the tip to form a small hook. The needles were inserted into the myocardium and then withdrawn, leaving the wires hooked into the epicardium.

The positions of the recording electrodes relative to the stimulating electrodes are shown in Figure 1. The two wires in each recording pair were separated by a distance of about 5 to 7 mm. Each pair of recording electrodes was connected to a differential alternating current amplifier (40 to 500 hertz). The bipolar electrograms and a lead II electrocardiogram were displayed on either a Gould-Brush (model 2800) or a Siemens-Elema (Mingograph 804) direct writing recorder at paper speeds of 100 to 250 mm/s.

Results

Response to a single stimulus to right ventricle: The application of high intensity currents to the ventricles during the vulnerable period of the cardiac cycle resulted in the appearance of abnormal extracellular electrical activity. Figure 2 illustrates a typical experiment in which abnormal local electrical activity was observed after the delivery of a single stimulus (10 ms) to the right ventricle during the vulnerable period of the cardiac cycle. The records show the surface electrocardiogram (lead II) and two bipolar right ventricular

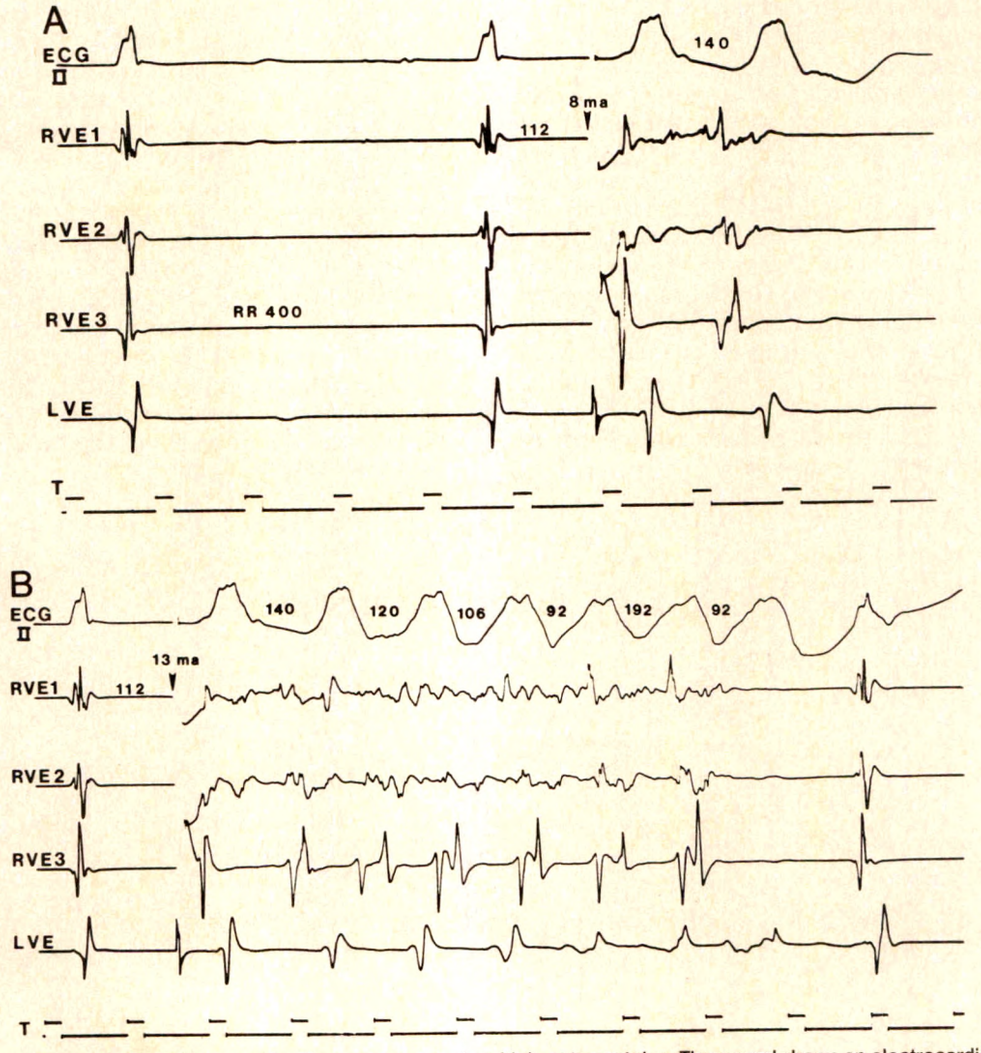

FIGURE 3. Continuous electrical activity preceding the appearance of multiple extrasystoles. The record shows an electrocardiogram (lead II) and four local electrograms (RVE1, RVE2, RVE3 and LVE). RVE1 and RVE2 were recorded from electrodes placed within 2 mm of the stimulating electrodes; RVE3 was recorded 5 mm away from the stimulating electrodes. LVE was obtained from the anterior left ventricle. The time lines (T) at the bottom of each panel indicate 100 ms intervals. **A,** after a control cycle, an 8 mA stimulus (**arrow**) is delivered to the right ventricle at a coupling interval of 112 ms, resulting in two ventricular extrasystoles (R-R interval 140 ms). **B,** the stimulus intensity is increased to 13 mA, resulting in a brief episode of ventricular tachycardia. The tachycardia accelerates during the first four cycles and oscillates in the fifth and sixth cycles before a normal rhythm is restored. In both panels the recording electrodes contiguous to the stimulating electrodes (RVE1 and RVE2) show continuous fractionated activity preceding the onset of each spontaneous ectopic complex. In contrast, RVE3 and LVE display isoelectric lines between successive ectopic complexes. However, the duration of the local activation complexes in these electrograms increases with progressive acceleration of the ectopic complexes.

electrograms (RVE1 and RVE2) recorded from electrodes contiguous to the stimulating electrodes (Fig. 1). Heart rate was held constant at a cycle length of 500 ms. In panel A, a 4 mA stimulus is delivered 180 ms after the intrinsic deflection in RVE2. A stimulus artifact can be seen in all three tracings; the largest is shown in the local bipolar electrograms. After occurrence of the stimulus artifact, a single premature ventricular complex is evident in the surface electrocardiogram, whereas both local electrograms show fractionated electrical activity lasting 110 ms beyond the onset of the stimulus. In panel B, an increase in the current intensity of the stimulus to 10 mA results in the production of two closely coupled extrasystoles in the surface electrocardiogram. Both of the local electrograms display fractionated electrical complexes that span the interval from the stimulus to the onset of the R wave of the second extrasystole in the electrocardiogram.

Figure 3 presents records from another experiment in which abnormal, local electrical activity resulted from ventricular stimulation during the vulnerable period of the cardiac cycle. The records show the surface electrocardiogram (lead II) and two bipolar electrograms (RVE1 and RVE2) recorded from electrodes placed on the right ventricle within 2 mm of the stimulating electrodes. Also shown are an electrogram recorded 5 mm below the stimulation site (RVE3) and one recorded from the anterior surface of the left ventricle (LVE). After the control cycle (Fig. 3A), an 8 mA stimulus is delivered to the right ventricle at a coupling interval of 112 ms. This stimulus results in two ventricular extrasystoles with an R-R coupling interval of 140 ms. The two electrograms recorded very close to the stimulating electrodes (RVE1 and RVE2) display continuous fractionated electrical activity that spans the interval between the two extrasystoles. In contrast to the marked fractionation at the stimulation site, the remote electrograms (RVE3 and LVE) show an isoelectric interval between two discrete activation complexes. The second complex in RVE3 is considerably longer than the first, indicating a more asynchronous spread of activity away from the stimulation site. In Figure 3B, the stimulus intensity is increased to 13 mA, resulting in a run of six spontaneous extrasystoles after the initial stimulus-induced extrasystole. The tachycardia exhibits acceleration during the first four cycles with an oscillation in the fifth and sixth cycles. The recording electrodes contiguous to the stimulating electrodes (RVE1 and RVE2) show continuous fractionated electrical activity throughout the duration of the ventricular tachycardia. In contrast, electrograms RVE3 and LVE show isoelectric interectopic intervals and an increase in the duration of the activation complexes with progressive acceleration of the premature complexes. Disappearance of the fractionated electrical activity in RVE1 and RVE2 is followed immediately by the resumption of a normal rhythm and the return of all electrograms to their control configuration. The morphologic features of the fractionated electrical complexes in both RVE1 and RVE2 show marked variations among successive cycles of the tachycardia. However, the morphologic features of the fractionated activity

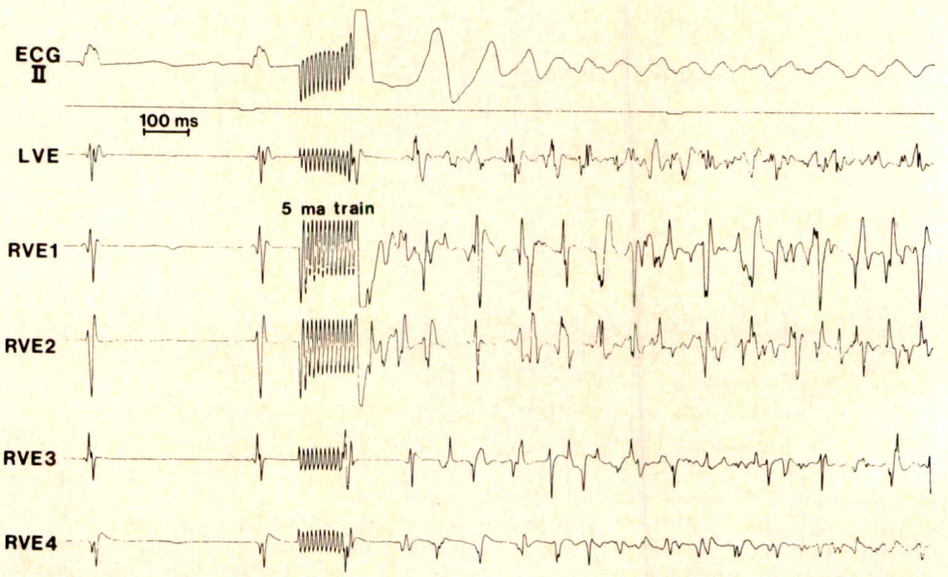

FIGURE 4. Continuous electrical activity evoked by a train of stimuli. Five bipolar electrograms (RVE1, RVE2, RVE3, RVE4 and LVE) are shown with a lead II electrocardiogram. RVE1 and RVE2 were recorded from electrodes placed within 3 mm of the stimulating electrodes. The two other right ventricular electrograms were recorded from electrode pairs placed 8 mm above (RVE4) and 20 mm below (RVE3) the stimulating electrodes. The remaining electrogram (LVE) was recorded from the anterior surface of the left ventricle. After a control cycle, a train of 14 pulses (4 ms, 100 hertz) is delivered to the right ventricle at a current intensity of 5 mA. The train results in a series of accelerating extrasystoles that degenerate into sustained fibrillation. Only the electrodes in close proximity to the stimulating electrodes (RVE1 and RVE2) record continuous electrical activity between the first and second extrasystoles. Once the extrasystoles have degenerated into sustained fibrillations, all of the local electrograms show continuous fractionated electrical complexes.

between the first two extrasystoles are similar to those of the fractionated activity recorded in Figure 3A.

Response to a train of stimuli scanning the T wave: Continuous fractionated electrical activity was also observed when trains of stimuli were used to scan the T wave of the electrocardiogram. Figure 4 shows the development of ventricular fibrillation after the delivery of a 5 mA train of pulses to the right ventricle. The records consist of a surface electrocardiogram (lead II) and five bipolar electrograms. The first two right ventricular electrograms (RVE1 and RVE2) were recorded 3 mm away from the stimulating electrodes, the third and fourth electrograms were recorded 20 mm below (RVE3) and 8 mm above (RVE4) the stimulating electrodes. The two pairs of recording electrodes contiguous to the stimulating electrodes (RVE1 and RVE2) show continuous fractionated electrical activity between the first and second extrasystoles; an isoelectric line is evident in the remote electrograms (LVE, RVE3 and RVE4). Once the initial extrasystoles degenerate into sustained fibrillation, all of the local electrograms display continuous fractionated electrical activity.

When recording electrodes were placed within 2 to 3 mm of the stimulation electrodes (*Fig. 1*) continuous fractionated electrical activity was consistently observed in all animals when either a single stimulus or a train of stimuli was used to evoke multiple extrasystoles or fibrillation. Trains of pulses initiated multiple extrasystoles and fibrillation at lower current intensities than did single pulses. Trains of pulses required an average of 7.0 ± 2.5 mA (±standard deviation) to fibrillate the heart; single stimuli required 15.2 ± 5.4 mA (difference highly significant [$p < 0.01$] by a paired t test). The current intensity needed to evoke multiple extrasystoles and fibrillation also resulted in saturation of the recording amplifiers and long-lasting artifacts (30 to 100 ms) in the bipolar electrograms. To minimize the possibility that the fractionated complexes were artifacts due to amplifier saturation, the coupling intervals of the single stimuli were varied in each animal. Although stimuli delivered after completion of the T wave or during the absolute refractory period were followed by large stimulus artifacts, no continuous fractionated electrical activity was recorded.

Effects of coupling interval on fractionated electrical activity: Figure 5 illustrates the effects of coupling interval on the appearance of fractionated electrical activity at the stimulation site. All records were obtained from the same experiment shown in Figure 4. A control cycle is shown in panel A (cycle length 493 ms). In panel B, a 10 mA stimulus applied to the right ventricle at a coupling interval of 190 ms results in two ventricular extrasystoles. The interval from the onset of the stimulus to the intrinsic deflection of the first extrasystole in RVE3 is 37 ms. Fractionated electrical activity, bridging the interval between the two extrasystoles, is observed only in RVE1 and RVE2. In panel C, the same 10 mA stimulus, delivered earlier in the relative refractory period at a coupling interval of 147 ms, is followed by a single ventricular extrasystole. The interval from the stimulus to the onset of the local activation complex in RVE3 is 87 ms, 45 ms longer than the stimulus-response interval shown in panel B. The longer stimulus-response interval in panel C presumably resulted from extremely slow impulse conduction away from the stimulation site due to excitation of

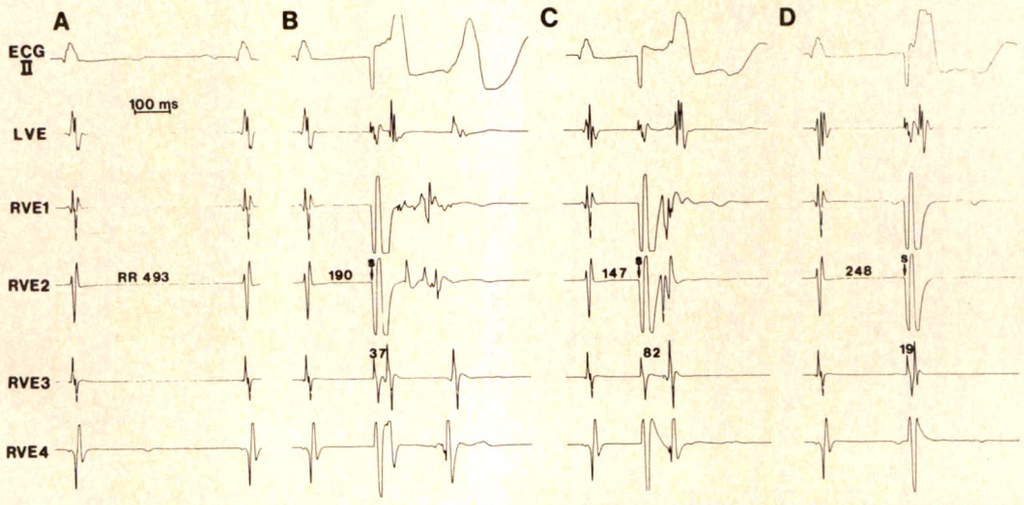

FIGURE 5. Effect of stimulus coupling interval on the appearance of fractionated electrical activity. The electrical recordings shown are identical to those in Figure 4. **A,** a control cycle. **B,** two ventricular extrasystoles in response to a 10 mA stimulus (s) delivered (**arrow**) during the vulnerable period (coupling interval 190 ms). Fractionated electrical activity bridging the interval between the two extrasystoles is apparent only in RVE1 and RVE2. **C,** the same stimulus is delivered earlier in the relative refractory period (coupling interval 147 ms), resulting in only a single ventricular response. The interval from the stimulus to the onset of activation in RVE3 is 82 ms, which is 45 ms longer than the stimulus-response interval in panel B. Although some fractionated electrical activity is recorded in RVE1 and RVE2 the activity disappears shortly after the onset of activation in RVE3 and RVE4. **D,** the 10 mA stimulus is delivered at the end of the T wave (coupling interval 248 ms), resulting in a single premature response. The longer coupling interval, as compared with those in panels B and C, is associated with a shorter stimulus-response interval (19 ms in RVE3). There is no fractionated electrical activity in RVE1 and RVE2 after recovery from the stimulus artifact.

myocardial cells very early in their relative refractory period. Although some fractionated electrical activity is recorded in the RVE1 and RVE2 electrograms immediately after the disappearance of the stimulus artifact, the activity disappears shortly after the onset of activation in RVE3 and RVE4. In panel D, the 10 mA stimulus, delivered at a coupling interval of 248 ms, results in a single ventricular extrasystole. The longer coupling interval in panel D compared with that in panels B and C is associated with a shorter stimulus-response interval (19 ms in RVE3). In contrast to the fractionated electrical activity after the stimulus in panel B, the RVE1 and RVE2 electrograms in panel I return to isoelectric conditions immediately after th stimulus artifact.

Effect of protective zone activation on fraction ated electrical activity: Further evidence indicatin that the fractionated electrical complexes after stimu lation during the vulnerable period were not artifact was provided by the finding that a second stimulu delivered during the protective zone totally abolishe the fractionated activity. Figure 6 illustrates this effe of activation of the protective zone on the productio of fractionated electrical activity. The records consis

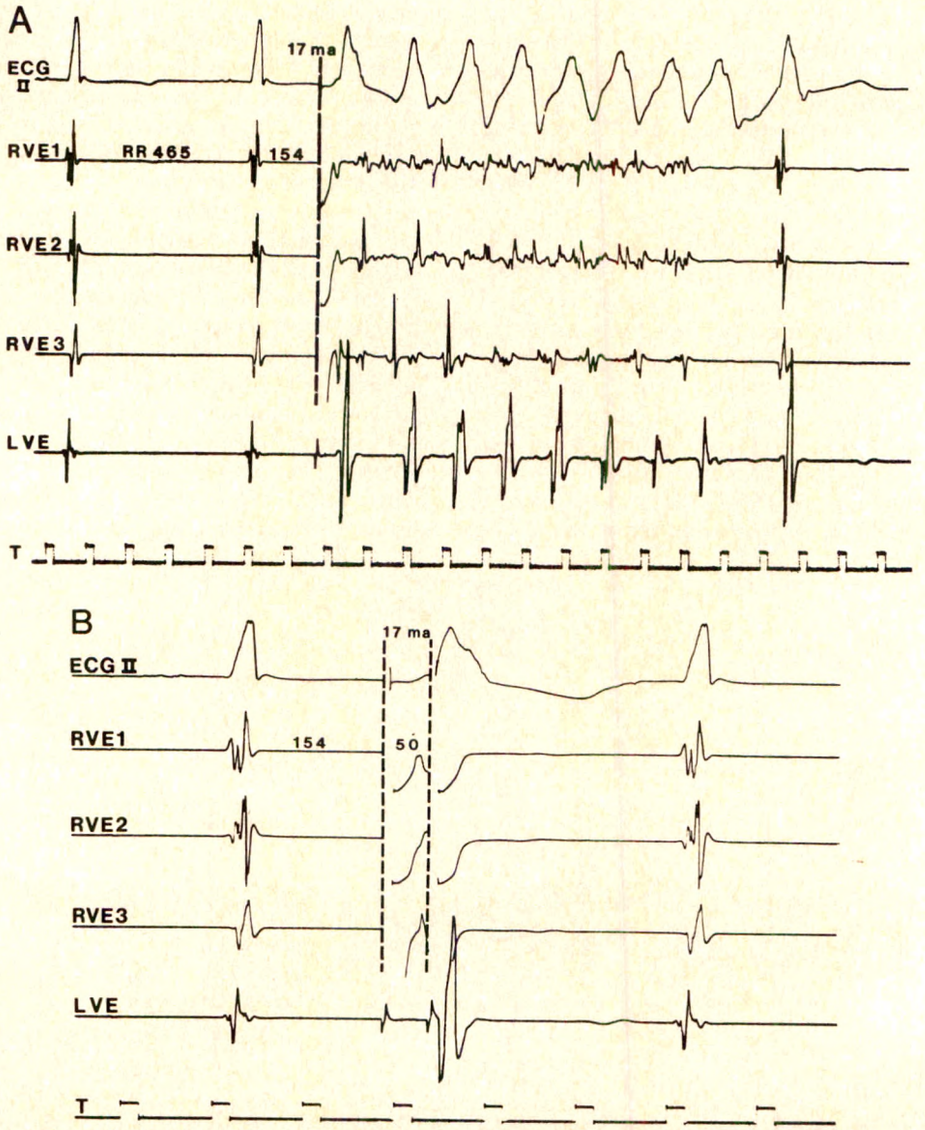

FIGURE 6. Effect of activation of the protective zone on the appearance of continuous electrical activity. The record shows four local electrograms (RVE1, RVE2, RVE3, LVE) and electrocardiographic lead II. The time marks (T) at the bottom of each panel indicate 100 ms intervals. RVE3 was recorded 4 mm below the stimulating electrodes; RVE1 and RVE2 were within 2 mm of the stimulating electrode. LVE was recorded from the anterior left ventricle. **A,** after a control cycle, a 17 mA stimulus (**broken line**) is applied to the right ventricle at a coupling interval of 154 ms. The stimulus results in a short run of ventricular tachycardia that spontaneously terminates after the seventh cycle. Only RVE1 and RVE2 show continuous fractionated electrical activity during the tachycardia. Disappearance of the continuous activity is followed immediately by termination of the tachycardia. **B,** an additional 17 mA stimulus is delivered 50 ms after the same stimulus that produced the repetitive extrasystoles in the left panel. The paper speed in the left panel is 100 mm/s; thus in the right panel is 250 mm/s. Although both stimuli produce large artifacts in the local electrograms there is no trace of fractionated electrical activity extending beyond the single premature response evoked by the stimuli.

of four local electrograms (RVE1, RVE2, RVE3 and LVE) and an electrocardiogram (lead II). Electrogram RVE3 was recorded 4 mm below the stimulating electrodes and RVE1 and RVE2 within 2 mm of the stimulating electrodes. After a control cycle (Fig. 6, left), a 17 mA stimulus is applied to the right ventricle at a coupling interval of 154 ms. The stimulus results in a short run of ventricular tachycardia that spontaneously terminates after the seventh cycle. Continuous fractionated electrical activity is recorded in electrograms RVE1 and RVE2 during the tachycardia; when this activity terminates, the tachycardia also terminates. In the right panel of Figure 6, an additional 17 mA stimulus is delivered 50 ms after an identical stimulus that produced the repetitive extrasystoles and continuous fractionated activity in the left panel. Although both stimuli produce large artifacts in the local electrograms, there is no trace of fractionated electrical activity extending beyond the single premature response evoked by the stimuli.

Discussion

Mechanisms involved in initiation of ventricular fibrillation: Ventricular fibrillation occurs when an organized activation wave front is fractionated into multiple asynchronous wavelets that propagate randomly through the myocardium. The arrhythmia may be induced either by a rapidly discharging automatic focus or by a reentrant circuit. Regardless of the mechanism of induction, fibrillation is sustained by multiple asynchronous reentry.

Although fibrillation is sustained by multiple reentry, the mechanism by which current delivered during the vulnerable period initiates fibrillation has not previously been elucidated. Several studies have indicated that changes in the ventricular fibrillation threshold are closely correlated with the amount of asynchrony in recovery of excitability among adjacent myocardial fibers.[8–12] Furthermore, Spear et al.[12] showed that either a single stimulus or a train of stimuli delivered during the vulnerable period at a central site results in an increase in temporal dispersion in recovery of excitability in tissue adjacent to the central site. They found that increasing the current intensity of either a single pulse or a train of pulses at the central site increased the temporal dispersion of refractoriness at the peripheral sites. They suggested that increasing the intensity of current delivered during the vulnerable period increased the degree of inhomogeneity in recovery of the myocardium until a level was attained that allowed multiple asynchronous reentry and fibrillation.

Although the ventricular fibrillation threshold is affected by interventions that alter the susceptibility of the heart to reentry, no study using direct recordings from the myocardium during the induction of fibrillation has been able to substantiate a reentrant mechanism. Moe et al.[4] suggested that a single stimulus of sufficient intensity delivered during the vulnerable period results in a single rhythmic center from which several impulses are discharged at an accelerating rate. They hypothesized that the progressive decrease in refractory periods associated with the accelerating rate and the conduction delay of the premature responses would establish the conditions necessary for reentry and fibrillation. Their conclusion that the initial accelerating extrasystoles originate from a single rhythmic center was supported by the observation of a similar spread of activation of each extrasystole on the surface and interior of the ventricles. The possibility of a macroreentrant circuit was eliminated because there was a period of time between each of the initial ectopic beats when no area of the ventricles was excited.[4]

Continuous local electrical activity preceding ventricular fibrillation: The results of our study do not support the concept of a single rhythmic center as the mechanism responsible for the genesis of multiple extrasystoles and fibrillation in response to either a single stimulus or a train of stimuli delivered during the vulnerable period. The observation of continuous fractionated electrical activity spanning the interval between the first premature complex and subsequent premature complexes (Figs. 2 to 6) suggests that the mechanism is much more complex than a single accelerating ectopic focus. In the experiments of Moe et al.,[4] electrograms were recorded from very close bipolar electrodes (interelectrode distance 1.5 mm) attached to the ventricles at least 6 mm from the site of stimulation. Presumably their failure to observe continuous fractionated electrical activity resulted from their failure to record from a sufficient mass of tissue in close proximity to the stimulating electrodes. In our experiments (Figs. 2 to 6), fractionated electrical activity was recorded only from wide bipolar electrodes placed very close to the stimulating electrodes. In electrograms recorded several millimeters away from the stimulation site, continuous electrical activity was not evident during the initial extrasystoles but usually appeared once the extrasystoles had degenerated into sustained fibrillation.

Although we were not able to determine the precise origin of the continuous electrical activity recorded in the vicinity of the stimulation site, the amplitude and rate of change of the majority of complexes suggest that they were associated with asynchronous depolarization of local myocardial fibers. Some of the electrical complexes may have been due to asynchronous repolarization of adjacent fibers, although the high pass filters employed presumably attenuated the potentials generated by repolarization to a much greater degree than those generated by depolarization.

It is possible that the continuous fractionated electrical activity recorded after the first extrasystole elicited by a train of stimuli or a single stimulus was not the cause of subsequent spontaneous extrasystoles, but was merely associated with their occurrence. However, the fact that local, fractionated electrical activity always spanned the diastolic interval before the onset of a spontaneous extrasystole argues for a cause and effect relation. In addition, during a run of multiple extrasystoles the disappearance of continuous fractionated electrical activity was followed immediately by the return of a normal rhythm (Fig. 3 and 6). Thus, the ap-

pearance of spontaneous extrasystoles after the initial stimulus-induced extrasystole was probably the result of the formation of multiple local wave fronts outlasting the refractory period of the surrounding myocardium. If the local wave fronts survived long enough, then the multiple extrasystoles degenerated into sustained fibrillation.

Origin of the continuous local electrical activity: Although the continuous fractionated electrical activity is suggestive of reentry, the possibility that multiple ectopic foci were discharging asynchronously must be considered. Moe et al.[4] suggested that a strong stimulus delivered during the vulnerable period creates a local state of tissue polarization that acts as a persisting stimulus resulting in multiple premature responses. In our present experiments, a long-lasting state of polarization created by a train or single stimulus might have produced multiple asynchronous firing of closely adjacent fibers, resulting in the appearance of continuous electrical activity in the local electrograms. However, if the initiation of fibrillation depended on a persisting stimulus due to tissue polarization, it would be difficult to account for the existence of a discrete vulnerable period. As shown in Figure 4, only stimuli delivered during the vulnerable period resulted in local, fractionated electrical activity that preceded the appearance of spontaneous extrasystoles. When stimuli were delivered earlier or later in the cardiac cycle, there was little such activity extending beyond the single premature response evoked by the stimulus.

It is also conceivable that the intense stimulus current could have triggered a series of asynchronous oscillatory afterpotentials in adjacent myocardial fibers, resulting in the appearance of continuous fractionated electrical activity in the local electrograms. However, afterpotentials always follow an action potential[12] and would not occur until after completion of the first premature action potential evoked by the stimulus. In our study, fractionated continuous electrical activity appeared immediately after the disappearance of the stimulus artifact, 30 to 100 ms after the delivery of the stimulus current. It is doubtful that the interval between the stimulus and the onset of continuous activity would be sufficient for completion of an action potential and generation of an afterpotential. Thus, our results suggest that both the initiation and the maintenance of fibrillation are due to local reentry.

Protective zone: Verrier et al.[13] found that in addition to a discrete vulnerable period, there is a discrete protective zone. This protective zone begins 10 to 15 ms after the nadir of the vulnerable period and has a duration of approximately 50 ms. A stimulus delivered during this time will prevent the development of fibrillation in response to a stimulus delivered during the vulnerable period. Activation of the protective zone in our study consistently abolished the continuous electrical activity that preceded the development of spontaneous extrasystoles and fibrillation. The protective zone occurs at a time when reentrant activity should be confined to a small mass of tissue in the immediate vicinity of the stimulation site. Thus, a strong stimulus delivered during this time could block reentry by depolarizing unexcited fibers in the circuit.

Comparison of fibrillation threshold techniques: The current required to produce continuous electrical activity and fibrillation with a train of pulses in our study was consistently less than that required for a single pulse. These observations are consistent with the lower fibrillation threshold that has been reported for a train of pulses.[14,15] The lower current level required for a train of pulses to initiate reentrant excitation may be due to complex interactions between individual pulses in a train.[15] Also, the current required for fibrillation when a train of pulses is used may depend on the timing of the pulses relative to the protective zone.[14] Furthermore, the discrepancy in the amount of current necessary to evoke fibrillation with the two techniques may depend largely on liberation of local stores of catecholamines by the stimuli. Euler[14] found that the elevation of the ventricular fibrillation threshold for a train of pulses in response to doses of propranolol sufficient to produce beta adrenergic blockade is seven-fold greater than the elevation in the threshold obtained with the single pulse technique. It is probable that the locally released stores of catecholamines increase the asynchrony in recovery of excitability of tissue adjacent to the stimulating electrodes, thereby facilitating the likelihood of reentry. Regardless of the precise mechanisms that result in the lower fibrillation threshold with a train of pulses than with a single pulse, the appearance of continuous fractionated electrical activity close to the stimulation site suggests that both methods initiate fibrillation by local reentry.

Electrophysiologic Effects of Disopyramide Phosphate on Reentrant Ventricular Arrhythmia in Conscious Dogs After Myocardial Infarction

EUGENE PATTERSON
JOHN K. GIBSON, PhD*
BENEDICT R. LUCCHESI, PhD, MD

Ann Arbor, Michigan

The electrophysiologic actions of disopyramide phosphate on reentrant ventricular tachycardia induced by premature ventricular stimuli were evaluated in conscious dogs 2 to 4 days after myocardial infarction. Disopyramide was administered as a series of intravenous infusions to obtain successive steady state plasma disopyramide concentrations of 1.02 ± 0.02, 2.05 ± 0.08, 3.94 ± 0.09 and 7.69 ± 0.18 μg/ml (mean values ± standard error of the mean). Disopyramide plasma concentrations of 1.02 ± 0.02 μg/ml produced an increase in the rate and duration of ventricular tachycardia as well as in the interval during which premature ventricular stimuli produced ventricular tachycardia. The effective refractory period of normal myocardium was decreased and conduction (activation time) was improved in ischemic myocardium. Increasing steady state plasma disopyramide concentrations slowed the rate of ventricular tachycardia without decreasing its duration. Slowing of the rate of tachycardia occurred simultaneously with a depression of conduction in normal and ischemic myocardium and an increase in ventricular refractoriness. Induction of ventricular tachycardia was prevented only at steady state plasma disopyramide concentrations of 7.69 ± 0.18 μg/ml. The results of this study suggest that subtherapeutic plasma concentrations of disopyramide may facilitate the development of reentrant ventricular arrhythmia in the electrically unstable heart. Ventricular tachycardia or fibrillation, or both, may be prevented only by plasma disopyramide concentrations that are in excess of the normal therapeutic range of 2 to 4 μg/ml.

Sudden death in patients with coronary artery disease results from severe disturbances of cardiac impulse formation or conduction that most often lead to ventricular fibrillation. Continuous electrical instability of the ischemic heart has been suggested as the primary factor leading to cardiac rhythm disturbances and can be exposed by the introduction of a critically timed premature ventricular stimulus that will initiate sustained ventricular tachycardia or ventricular fibrillation, or both.[1–5]

Studies of drugs that will prevent reentrant ventricular arrhythmia have been extensive in recent years, but have been hampered by the lack of a suitable animal model capable of identifying pharmacologic agents with the ability to reduce the incidence of ventricular fibrillation in the chronically ischemic heart. In most animal models used in the study of antiarrhythmic drugs, myocardial ischemia is created by acute coronary arterial ligation. Although this procedure will lead to ventricular fibrillation in a large proportion of the trials, the electrical events do not simulate the chronic electrical instability associated with sudden coronary death.[6] In addition, ventricular tachycardia present 24 to 48 hours after experimental coronary arterial occlusion rarely culminates in ventricular fibrillation and is believed to be due to enhanced automa-

ticity in Purkinje fibers.[6,7] Recently, it was demonstrated that a critically timed electrically induced premature ventricular stimulus could initiate reentrant ventricular tachyarrythmia and ventricular fibrillation in dogs 2 to 9 days after acute myocardial infarction. This reentrant electrical activity also simulated that observed in patients in whom reentrant rhythms could be induced by programmed electrical stimulation of the heart.[8,9]

This study was undertaken for the purpose of evaluating the ability of disopyramide phosphate to prevent reentrant arrhythmia resulting from programmed electrical stimulation in the presence of chronic myocardial ischemia. The electrophysiologic effects of disopyramide phosphate were evaluated in relation to drug plasma concentrations. The results of these studies in the conscious dog with experimentally induced chronic myocardial ischemia demonstrate that disopyramide in clinically recommended plasma concentrations (2 to 4 μg/ml) is unlikely to be beneficial in preventing reentrant ventricular tachyarrhythmia; this prevention can only be accomplished with plasma concentrations in excess of 4 μg/ml.

Methods

Animal preparation: Male mongrel dogs weighing between 14.2 and 18.0 kg were anesthetized with intravenous sodium pentobarbital, 30 mg/kg body weight. Each animal was intubated with a cuffed endotracheal tube and ventilated with room air using a Harvard respirator. With use of aseptic techniques, sterile catheters were implanted in the left common carotid artery and left external jugular vein and passed subcutaneously to the surface through an incision in the back of the neck. A left thoracotomy was performed in the fourth intercostal space and the heart was suspended in a pericardial cradle. A 5 mm section of the left anterior descending coronary artery was dissected free from the surrounding myocardium at the tip of the left atrial appendage. A length of suture was passed around the artery and a 20 gauge needle, then securely tied and the needle withdrawn. Left anterior descending coronary arterial flow was monitored using an electromagnetic flow probe (Carolina Medical Electronics) before and after stenosis to ensure that coronary flow at rest was undisturbed. Silastic® tubing was used to occlude coronary flow for a period of 90 minutes and then flow was allowed to return through the stenosed artery. Lidocaine hydrochloride, 5 mg/kg intravenously followed by 5 mg/kg intramuscularly, was given to those animals manifesting severe ventricular arrhythmia on reinstitution of coronary flow.

Electrical placements: A bipolar electrode was sewn onto the surface of the left atrial appendage. A second bipolar plunge electrode (28 gauge stainless steel, 5 to 7 mm in length) was placed on the right ventricular outflow tract with the exposed electrode tips placed in the interventricular septum.

Bipolar composite electrodes were placed on the epicardial surface of the left ventricle. One bipolar composite electrode was placed over normal myocardium and the second was placed over ischemic and infarcted myocardium. Correct placement of the bipolar composite electrodes was established at autopsy. The electrode wires were exited through the chest and passed subcutaneously to the back of the neck. The chest was closed in layers and procaine penicillin G, 1.2 million units, was administered intramuscularly.

Electrophysiologic studies: Forty-eight hours after myocardial infarction, the animals were conscious and resting comfortably, supported in a sling. Arterial pressure was monitored with a Statham P23DC pressure transducer and recorded on a Grass model 7 polygraph. A lead II electrocardiogram was monitored continuously and recorded. Bipolar composite electrograms, an atrial bipolar electrogram and a lead II electrocardiogram were recorded on a Honeywell model 1858 Visicorder filtered at 15 to 2,500 hertz. If the ventricular ectopic rate was greater than 10 beats/min, the animal was returned to its quarters and monitored 24 hours later. If the rate was 10 beats/min or less, the following procedure was used: A Grass model SD_5 stimulator was used to deliver square wave impulses, 3 ms in duration, at a voltage twice the diastolic threshold for atrial or ventricular pacing (S_1 stimuli). A Tektronix model 565 oscilloscope and differential amplifier were used to trigger the output of a Grass model S88 stimulator at the peak of the R wave of the lead II electrocardiogram. A Grass model S88 stimulator and SIU5 stimulus isolation unit delivered 3 ms square wave pulses (S_2 and S_3 stimuli) at selected delays after the peak of the R wave to the bipolar electrode located in the interventricular septum. Diastolic threshold was determined 200 ms after the peak of the R wave. All subsequent premature stimuli delivered to the interventricular septum were 1.5 times diastolic threshold.

The effective refractory period of the left ventricular myocardium was determined using square wave pulses (1.5 times threshold, 3 ms in duration) and decreasing the R to S_2 interval until a conducted beat was not generated. Activation times (Q-EG intervals), the delay from the Q wave of the lead II electrocardiogram to the major positive spike of the normal zone or ischemic zone epicardial bipolar composite electrograms, were determined during atrial pacing at a rate of 175 beats/min. All electrophysiologic measurements were made from recordings performed at a paper speed of 100 to 400 mm/s.

Administration of disopyramide: Disopyramide phosphate was administered by a series of two stage intravenous infusions as described by Wagner.[10] The values for apparent volume of distribution (2.01 liters/kg), alpha phase elimination constant (44.4 $hour^{-1}$), and beta phase elimination constant (0.55 $hour^{-1}$) were obtained from earlier pharmacokinetic studies.[11,12] The infusion protocol was designed to reach and maintain successive steady state disopyramide plasma levels of 1, 2, 3, 4, and 8 μg/ml. An infusion of disopyramide at a rate of 23.3 mg/kg per hour for 4 minutes was followed by a second infusion of 1.09 mg/kg per hour designed to maintain plasma disopyramide concentrations of 1 μg/ml. The infusion rate was increased to 24.4 mg/kg per hour for 4.0 minutes followed by an infusion at a rate of 2.18 mg/kg per hour to maintain plasma concentrations of 2 μg/ml. The infusion rate was increased again to 24.4 mg/kg per hour for 4.8 minutes followed by an infusion at a rate of 3.28 mg/kg per hour to maintain plasma concentrations of 3 μg/ml. To increase the steady state plasma concentrations to 4 μg/ml, the infusion rate was increased to 24.4 mg/kg per hour for 5.3 minutes followed by an infusion at a rate of 4.37 mg/kg per hour to maintain steady state concentrations. Steady state plasma disopyramide concentrations of 8 μg/ml were achieved by increasing the infusion rate to 101.9 mg/kg per hour for 5 minutes followed by an infusion at a rate of 8.72 mg/kg per hour. A period of 20 minutes was allowed to pass at each steady state plasma concentration before electrophysiologic testing was initiated. Disopyramide phosphate was administered using a Harvard model 975 infusion pump.

Determination of plasma disopyramide concentration: Blood samples (3 ml) were collected in 5 ml tubes containing 500 units of sodium heparin. Plasma disopyramide concentrations were determined with the gas chromatographic method of Patterson et al.[13] Plasma samples were taken just

before and after electrophysiologic testing at each steady state plasma level. Plasma potassium concentrations were determined from these samples with use of flame spectrophotometry.

Determination of infarct size: The animals were anesthetized with sodium pentobarbital, 20 mg/kg intravenously. The heart was excised, rinsed briefly in cold water and sliced from apex to base into 1 cm thick sections. The slices were incubated in 0.2 percent triphenyltetrazolium in 0.1 *M* phosphate buffer, pH 7.4, at 40°C for 15 minutes. Infarct size was determined gravimetrically and expressed as a percent of total left ventricular mass.

Materials: Disopyramide phosphate and p-chlorodisopyramide phosphate were obtained from the G.D. Searle Company. Triphenyltetrazolium was purchased from the Sigma Chemical Company. All other chemicals were reagent grade.

Statistical methods: Numerical values are expressed as the mean ± standard error of the mean. Differences between groups were analyzed by analysis of variance.

Results

Rate-dependent conduction disorders: Two to 4 days after myocardial infarction, the ventricular ectopic rate had decreased to 3 ± 1 complexes/min, and the animals were entered into the study protocol. Composite bipolar electrodes were used to record left ventricular myocardial activation. Activation of ischemic myocardium was prolonged (82 ± 13 ms) compared with activation of normal myocardium (49 ± 11 ms) (Table I). Left atrial pacing was used to increase sequentially the ventricular rate to 300 beats/min or until the development of atrioventricular dissociation. As the ventricular rate increased, there was a significant increase in the duration of activation of ischemic myocardium whereas no change was seen in the duration of electrical activity in normal left ventricular myocardium (Table I). A further increase in the ventricular rate produced fractionation of the ischemic zone bipolar composite electrogram (Fig. 1).

Induction of ventricular tachycardia: Two to 4 days after myocardial infarction, programmed electrical stimulation was used to initiate reentrant rhythm in the conscious dogs. Premature ventricular stimuli were introduced during both normal sinus rhythm (cycle lengths 357 to 501 ms) and atrial pacing (cycle lengths 284 to 454 ms). No differences were observed between the duration or rate of ventricular tachycardia induced in any one animal by single or double premature stimul during either normal sinus rhythm or atrial pacing, anc therefore the data are grouped in Table II. In thre animals, sustained ventricular tachycardia lasting i excess of 2 minutes was observed. Four of eight episode were self-terminating. Episodes of sustained ventricula tachycardia producing hypotension were terminate with single premature ventricular stimuli (Fig. 2). In on animal, ventricular tachycardia proceeded to ventric ular fibrillation within 10 seconds of introduction of a single premature stimulus.

Electrophysiologic effects of steady state plasma disopyramide concentrations of 1 μg/ml: Disopyramide plasma concentrations of 1.02 ± 0.02 μg/ml increased both the rate and duration of the induced ventricular tachycardia and duration of ischemic zone asynchronous electrical activity (Table II, Fig. 3 and 4). The interval during which ventricular tachycardia could be induced (induction period) also was increased. The critical coupling interval was increased for ventricular tachycardia induced by single (S_2) or double (S_2 and S_3) premature stimuli. Sustained ventricular tachycardia now could be induced in two animals in which only nonsustained ventricular tachycardia could be induced before administration of disopyramide. The changes occurred simultaneously with a decrease in the ventricular effective refractory period and a decrease in activation times of the ischemic myocardium (Table III). However, the cycle lengths at which Wenckebach-like conduction of ischemic potentials occurred

TABLE I

Duration of Electrical Activation of Ventricular Myocardium 48 Hours After Myocardial Infarction

Cycle Length (ms)	Duration of Activation (ms)	
	Normal Zone	Ischemic Zone
430 ± 23	49 ± 11	82 ± 13†
253 ± 12	46 ± 8	106 ± 19*

*,† Probability [p] values: * <0.05, compared with ischemic zone electrical activation duration at a cycle length of 430 ± 23 ms, † <0.05 compared with normal zone.

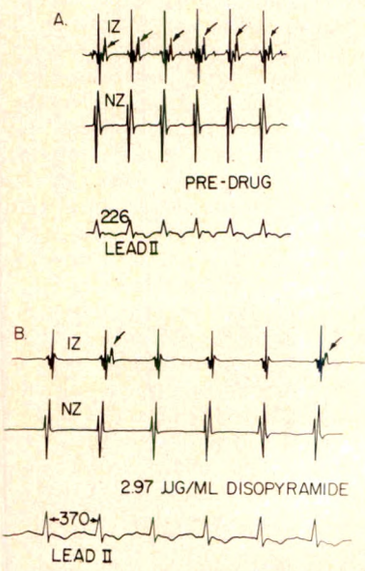

FIGURE 1. Conduction in ischemic myocardium—effect of disopyramide. **A,** before administration of disopyramide, atrial pacing decreases the ventricular cycle length to 226 ms; at this cycle length, fractionation of ventricular activation occurs. Slightly shorter cycle lengths produced Wenckebach-like conduction of these ischemic potentials (not shown). **B,** at disopyramide plasma concentrations of 2.97 μg/ml, Wenckebach-like conduction (3:1) occurs at a cycle length of 370 ms. Ischemic electrical potentials are marked by **arrows.** IZ = ischemic zone; NZ = normal zone.

TABLE II

Electrophysiologic Variables

Plasma Disopyramide Concentration (μg/ml)	Reentrant Beats (n)	Cycle Length of Ventricular Tachycardia (ms)	Duration of Asynchronous Activity (ms)	Induction Period (ms)	
				S_2	S_3
(before drug administration)	6.2 ± 0.8	163 ± 6	1005 ± 83	25 ± 2	37 ± 4
1.02 ± 0.02	8.4 ± 0.8*	155 ± 2*	1195 ± 87*	42 ± 4*	48 ± 4*
2.05 ± 0.08	5.5 ± 0.8	193 ± 8*	990 ± 81	24 ± 6	34 ± 4

were not altered from the values before drug administration.

Electrophysiologic effects of increasing plasma disopyramide concentrations: Plasma disopyramide concentrations were increased sequentially to steady state concentrations of 2.05 ± 0.08, 2.99 ± 0.03, 3.94 ± 0.09 and 7.69 ± 0.18 μg/ml. These increases produced a concentration-dependent increase in the cycle length of ventricular tachycardia without shortening the duration of the tachycardia until plasma levels of 7.69 ± 0.18 μg/ml were attained (Table II, Fig. 3 and 4). The induction periods for the premature stimuli S_2 and S_3 were reduced sequentially by increasing plasma disopyramide concentrations, although ventricular tachycardia could be induced in all animals at plasma disopyramide concentrations of 3.94 ± 0.09 μg/ml. The slowing of the rate of tachycardia occurred simultaneously with the depression of cardiac conduction, as reflected in the concentration-dependent increase in the cycle length of the ventricular arrhythmia and the increase in the activation times of normal and ischemic myocardium. Increasing plasma disopyramide concentrations also produced sequential increases in ventricular refractoriness (Table III).

Disopyramide plasma concentrations of 7.69 ± 0.18 μg/ml were necessary to suppress completely the induction of ventricular tachycardia. In several instances, single or double reentrant beats were seen (Fig. 3), but longer runs of ventricular tachycardia could not be induced. The elevated disopyramide plasma concentration produced considerable conduction delay in normal and ischemic myocardium and produced a 23 ms increase in the effective refractory period of the normal left ventricular myocardium (Table III).

Plasma potassium concentrations: Plasma potassium concentrations were determined before and after electrophysiologic testing at each steady state plasma disopyramide concentration as well as before adminis-

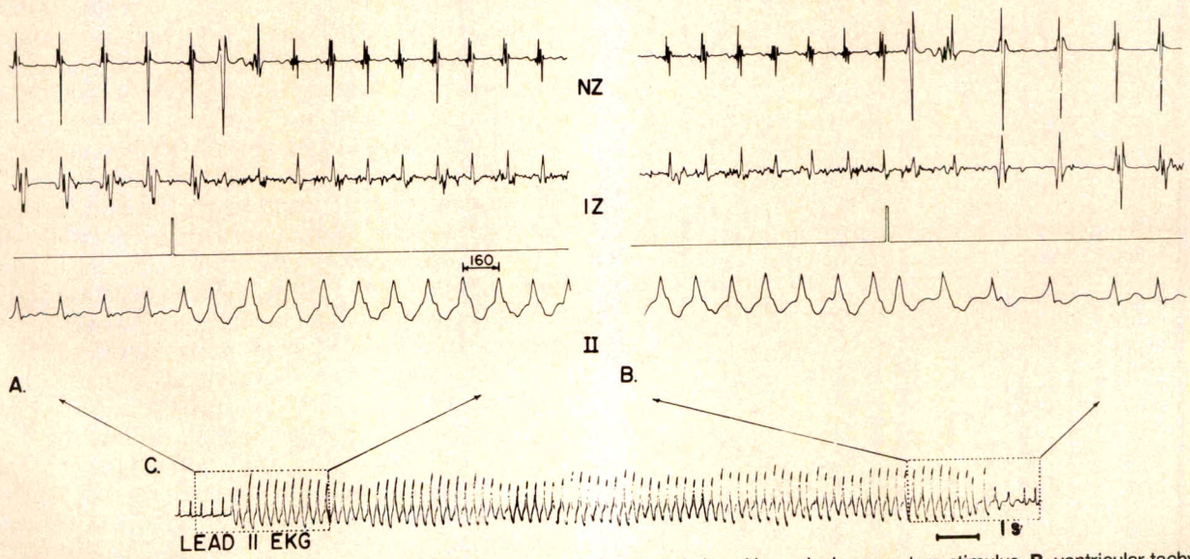

FIGURE 2. Sustained ventricular tachycardia. **A,** sustained ventricular tachycardia is induced by a single premature stimulus. **B,** ventricular tachycardia is terminated by a single premature impulse because of hypotension. Premature stimuli are marked by **narrow rectangles** in **A** and **B.** Electrical activation of normal myocardium (NZ) remains discrete during ventricular tachycardia although ischemic zone (IZ) activation was continuous. Activation of normal and ischemic myocardium was measured with bipolar composite electrodes. EKG = electrocardiogram.

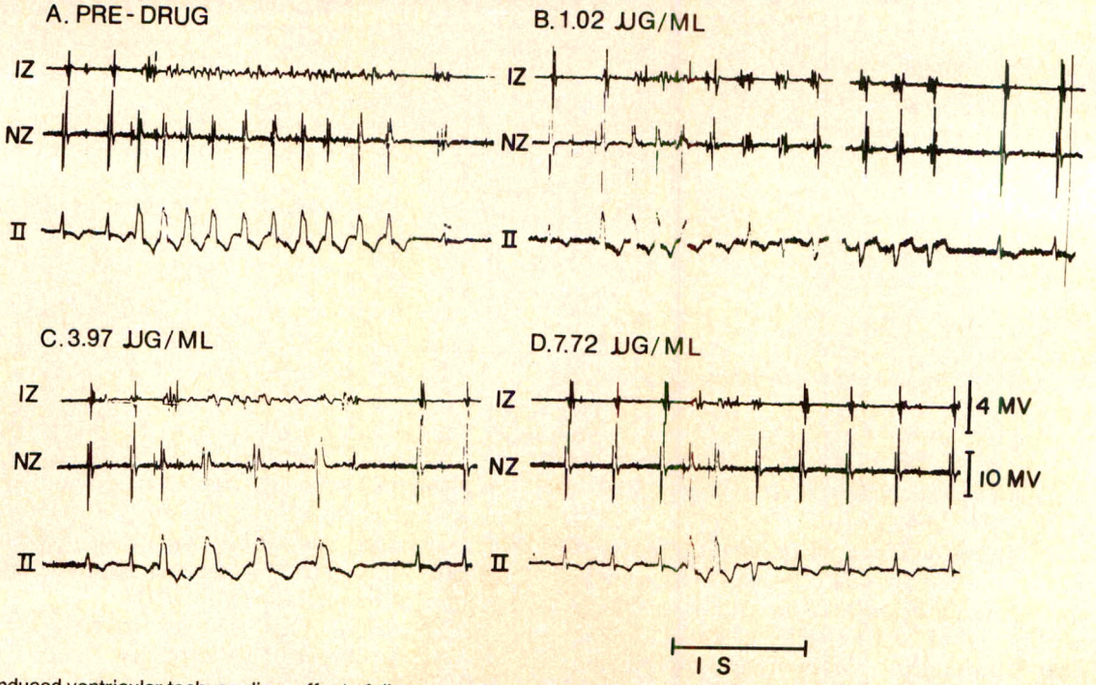

FIGURE 3. Induced ventricular tachycardia—effect of disopyramide. **A,** before administration of disopyramide, a single premature stimulus elicits a nine beat ventricular tachycardia with a cycle length of 225 ms. **B,** at a plasma disopyramide concentration of 1.02 μg/ml, a single premature stimulus produces sustained ventricular tachycardia at a cycle length of 216 ms. The ventricular tachycardia was sustained for 2 minutes and 45 seconds, after which spontaneous slowing and termination were seen. **C,** at a plasma disopyramide concentration of 3.97 μg/ml, a single premature stimulus elicits a ventricular tachycardia of three beats having a cycle length of 419 ms. **D,** at a plasma disopyramide concentration of 7.72 μg/ml, two premature stimuli produce a single reentrant beat. Activation of normal myocardium (NZ) remained discrete in the composite electrogram whereas ischemic zone activation (IZ) was continuous during ventricular tachycardia.

tration of disopyramide. Before administration of disopyramide, the plasma potassium concentration was 3.8 ± 0.1 mEq/liter and did not change significantly throughout the course of the experiment.

Infarct size: Occlusion of the left anterior descending coronary artery for a period of 90 minutes followed by reperfusion of the ischemic myocardium produced infarct masses of 3.2 to 34.6 g, representing 3.0 to 34.0 percent of the left ventricular mass (mean 19.4 ± 3.8 percent). The infarcts were located subendocardially and did not extend to the epicardial surface.

TABLE III

Effective Refractory Periods and Changes in Q-EG Interval (mean values ± standard error of the mean)

Plasma Disopyramide Concentration (μg/ml)	Effective Refractory Periods (ms)	ΔQ-EG (ms)	
		Normal Zone	Ischemic Zone
(before drug administration)	142 ± 8	...	...
1.02 ± 0.02	138 ± 9*	−0.2 ± 0.3	−3.9 ± 1.6*
2.05 ± 0.08	146 ± 8*	0.2 ± 0.3	4.2 ± 0.9*
2.99 ± 0.03	147 ± 9*	0.6 ± 0.2*	7.6 ± 1.2*
3.94 ± 0.09	148 ± 10*	1.9 ± 0.6*	9.8 ± 0.9†

* $p < 0.05$, † $p < 0.01$ compared with values before drug administration.

Q-EG = interval from the initiation of the Q wave of lead II to the major deflection in the bipolar electrogram; ΔQ-EG = change from the value obtained before drug administration (value before drug administration = 0).

Discussion

Improved activation in ischemic myocardium and induction of reentrant tachyarrhythmia with subtherapeutic concentrations: Steady state plasma disopyramide concentrations of 1.02 ± 0.02 μg/ml increased the duration and decreased the cycle length of reentrant ventricular tachycardia. This action is not unique to disopyramide: El-Sherif and Lazzara[14] have shown verapamil to improve conduction in ischemic canine myocardium by improving depressed phase 0 maximal upstroke velocity of Purkinje fibers. In addition, verapamil has been shown to decrease the cycle length of reentrant ventricular tachycardia and to increase the incidence of ventricular fibrillation in dogs 3 to 5 days after myocardial ischemic injury.[15] Although there are few similarities in the mechanisms of action of disopyramide and verapamil, these data suggest that improvement of depressed conduction in ischemic myocardium may result in increased rates of ventricular tachycardia and an increased incidence of ventricular fibrillation.

Reddy and co-workers[16,17] demonstrated that subtherapeutic concentrations of procainamide facilitated the induction of tachyarrhythmia in human subjects. Nonsustained ventricular tachycardia became sustained

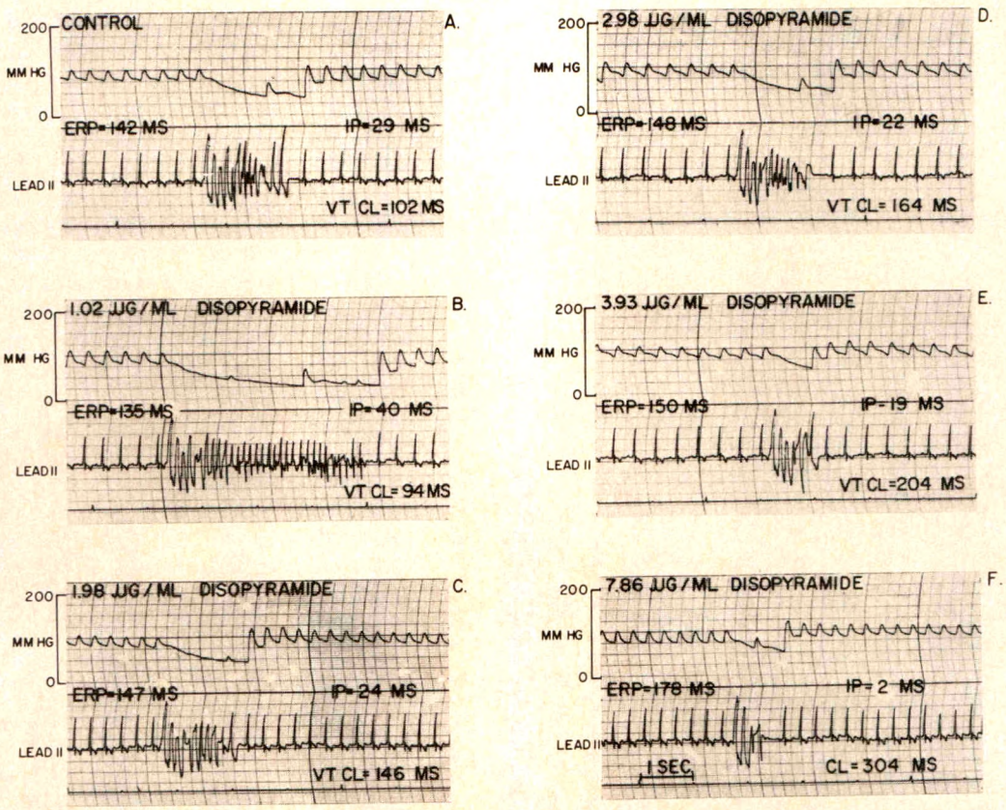

FIGURE 4. Induced ventricular tachycardia—effect of disopyramide. Lead II electrocardiograms and arterial blood pressure tracings are shown before and after administration of disopyramide. **A,** double premature stimuli produce a 10 beat run of ventricular tachycardia with a cycle length (VT CL) of 102 ms. **B,** at a plasma disopyramide concentration of 1.02 μg/ml, the tachycardia increases to 20 beats at a cycle length of 94 ms after two premature stimuli. The period of induction of tachycardia (IP) increases from 29 to 40 ms whereas the effective refractory periods (ERP) is reduced from 142 to 135 ms. **C,D,E,** increasing plasma disopyramide concentrations of 1.98, 2.98 and 3.93 μg/ml produce lengthening of the cycle lengths of the induced ventricular tachycardia to 146, 164 and 204 ms, respectively, and decrease the duration of the ventricular tachycardia. Only modest reductions of the induction periods and small increases in the effective refractory periods are seen. **F,** two premature stimuli produce a reentrant couplet with a cycle length of 304 ms. The induction period of this couplet was 2 ms.

after administration of procainamide, and reentrant rhythms could be induced only after its administration. Horowitz et al.[18] observed similar results when they administered procainamide to survivors of apparent sudden coronary death whose nonsustained reentrant rhythm became sustained ventricular tachycardia. They reported that a decrease in conduction velocity occurred simultaneously with facilitated reentry and postulated that procainamide facilitated reentry by slowing conduction velocity to a greater degree than it increased ventricular refractoriness. Larger doses of procainamide prevented the induction of reentrant cardiac rhythms. In our study with disopyramide, depression of cardiac conduction was not observed at the time when the periods required for induction of reentrant rhythms were increased; rather, there was an improvement in myocardial activation in ischemic myocardium.

The electrophysiologic actions of subtherapeutic concentrations of disopyramide have not previously been investigated. However, "therapeutic concentrations" of disopyramide have been shown to produce decreases in the rate of phase 0 depolarization of canine Purkinje fibers[19–21] and in myocardial conduction velocity.[22] Improvement in cardiac conduction has not been reported. The direct depressant actions of disopyramide may predominate at higher concentrations whereas at lower concentrations the drug might act indirectly through an antagonism of muscarinic cholinergic receptors.[22–25]

Increased activation time and ventricular refractoriness with high plasma concentrations: Increasing plasma concentrations of disopyramide produced progressive increases in ventricular activation times and in ventricular refractoriness in normal and ischemic myocardium. The increases in activation times of ischemic myocardium were greater than those in normal myocardium. Slowing of the cardiac impulse through ventricular myocardium comprising the reentry circuit is a possible factor involved in the slowing of the ventricular tachycardia after administration of disopyramide, although the role of increased myocardial refractoriness is unknown.

Increasing steady state disopyramide plasma concentrations slightly reduced the periods required for induction of ventricular tachycardia. Reduction of this critical interval may be somewhat beneficial, but com-

plete prevention of the induction of ventricular tachycardia may be necessary for prevention of sudden coronary death. Ruskin and Garan[26] demonstrated that antiarrhythmic drug therapy that renders ventricular tachycardia noninducible by programmed cardiac stimulation constitutes effective prophylaxis against spontaneous recurrent sustained ventricular tachycardia in the majority of patients studied. Josephson et al.[27] showed that failure to maintain plasma concentrations of antiarrhythmic drugs at levels previously shown to be effective in preventing the induction of sustained ventricular tachycardia can lead to the recurrence of sustained ventricular tachycardia or sudden coronary death. The 25 to 40 percent reduction in the period required for induction of sustained tachycardia, seen in our study at plasma disopyramide concentrations of 3.94 ± 0.09 μg/ml, may be ineffective in preventing sudden coronary death because only concentrations of 7.69 ± 0.18 μg/ml prevented electrical induction of ventricular tachyarrhythmia (Table II).

It is not surprising that high plasma disopyramide concentrations are needed for suppression of induction of ventricular tachycardia. Benditt et al.[28] reported that disopyramide plasma concentrations that prevented the induction of ventricular tachycardia in human subjects were in excess of 3 μg/ml (mean nearly 5 μg/ml). Similarly, procainamide's effectiveness was reported to require plasma concentrations in excess of 9 μg/ml whereas quinidine plasma concentrations necessary for prevention of induction of ventricular tachycardia were in excess of 3 μg/ml.[25–27] Thus, the plasma concentrations of antiarrhythmic agents necessary for prevention of sudden coronary death may be higher than currently accepted "therapeutic concentrations." However the "high" plasma concentrations of antiarrhythmic drugs may prove to have deleterious actions on cardiac electrophysiology and myocardial function.[29–31]

Clinical implications: The majority of cardiac deaths are sudden and most likely due to a "primary" arrhythmic event most often characterized by ventricular fibrillation. Endeavors to prevent sudden coronary death with pharmacologic means have resulted in numerous reports in which drugs have been claimed to be "effective" solely because of their ability to reduce the frequency of premature ventricular complexes. This study, although conducted in the experimental animal, might provide some important insights into an understanding of why there often exists a lack of a predictable relation between the ability to suppress chronic asymptomatic complex ventricular arrhythmia and ventricular fibrillation or sudden coronary death. As demonstrated in the canine model using programmed cardiac stimulation in the presence of latent electrical instability, concentrations (2 to 4 μg/ml) of disopyramide known to reduce or prevent complex premature depolarizations were unable to prevent the induction of sustained reentrant ventricular tachyarrhythmia. The suggestion that recurrent episodes of ventricular tachycardia or ventricular fibrillation, or both, might be prevented by relatively high plasma concentrations of disopyramide has important implications with respect to future clinical trials designed to explore the prophylactic use of this drug in the patient at risk of sudden coronary death. A beneficial effect might not be realized if such trials follow current "therapeutic" guidelines in suggesting maintenance of plasma concentrations of 2 to 4 μg/ml. However, the negative inotropic effect of disopyramide may preclude the use of higher dosage regimens in patients with compromised left ventricular function.

We are entering an era in which the pharmacologic prevention of sudden coronary death may soon become a reality. The task of identifying the proper agent or agents will not be a simple one; a single approach to the prevention of ventricular fibrillation is probably not attainable because the arrhythmia probably results from the interplay of many mechanisms, the most important of which is an acute or chronic state of electrical instability. The animal model used in our study has the advantage over previous models of more closely representing the clinical state associated with sudden coronary death. It may be useful in exploring the pathophysiologic processes that render the myocardium vulnerable to ventricular fibrillation and in studying how pharmacologic agents act to prevent a fatal electrical event.

The No Reflow Phenomenon: A Time-Limiting Factor for Reperfusion After Coronary Occlusion?

JOHN R. DARSEE, MD*
ROBERT A. KLONER, MD, PhD

Boston, Massachusetts

A study was performed in 33 dogs to ascertain (1) whether the "no reflow" phenomenon is a critical factor determining the time beyond which revascularization can no longer salvage ischemic myocardium, and (2) whether reperfusion damages tissue not otherwise destined to become necrotic. Twelve dogs were subjected to 2 hours of coronary occlusion followed by 4 hours of reperfusion, 10 dogs to 4 hours of occlusion followed by 2 hours of reperfusion and 11 dogs to 6 hours of coronary occlusion alone. The area of "no reflow" was determined by injecting a fluorescent dye into the left atrium at the end of 6 hours with the coronary artery patent, and the ischemic area at risk by injecting methylene blue dye into the left atrium with the coronary artery reoccluded. The area of necrosis on all 5 mm transverse ventricular sections was determined by incubation in triphenyltetrazolium chloride stain and compared with its respective area at risk and area of no reflow. In all dogs the no reflow area was always significantly smaller than, and contained topographically within, the area of necrosis. Furthermore, the area of necrosis expressed as a percent of the area at risk was significantly smaller for dogs with 2 or 4 hours of occlusion and reperfusion than for dogs with longer periods of occlusion and briefer periods of reperfusion. It is concluded that (1) the no reflow phenomenon does not determine the critical time for salvageability of myocardium by revascularization because the area of no reflow is surrounded by necrotic but reperfusable tissue, and (2) reperfusion does not increase the quantity of ischemic tissue that becomes necrotic.

During the last decade many interventions have been shown experimentally to protect ischemic myocardium from necrosis.[1–3] One of the most attractive of these experimental methods is early reperfusion because it has direct application to treatment of clinical myocardial ischemia with coronary vasodilator agents,[4] intracoronary streptokinase administration and coronary arterial bypass grafting.[5] A potentially important complicating aspect of early reperfusion is the "no reflow" phenomenon, which has been defined in the canine heart as a region of myocardium that does not allow normal reflow of blood during reperfusion after experimental coronary occlusion of 90 minutes or longer.[6] The no reflow phenomenon is one of several controversial issues concerning reperfusion, all related to whether early reperfusion is beneficial to ischemic myocardium, or whether it causes more tissue and vascular damage than that resulting from sustained coronary occlusion. Specifically, there is considerable debate regarding the role of microvascular injury that occurs as a consequence of ischemia. It is not clear whether it is a result of the necrotic process or whether it prevents reperfusion from salvaging ischemic but viable myocardial tissue, thereby increasing the extent of necrosis.

The present study was designed to characterize the spatial geometry and regional myocardial blood flow of the area of no reflow and to determine whether the no reflow phenomenon contributes to necrosis or

is a result of the necrotic process in tissue already irreversibly injured and therefore not salvageable by any intervention including reperfusion. A secondary goal was to determine whether the no reflow phenomenon, or the development of a nonperfusable region of myocardium, is a time-limiting factor determining the extent to which reperfusion or revascularization can salvage ischemic myocardium. The answer to this question would have a profound influence on the feasibility and success of early revascularization in human beings.

Methods

Experimental preparation: Forty-one mongrel dogs of either sex weighing 20 to 34 kg were anesthetized with thiamylal sodium (30 mg/kg body weight intravenously), intubated and ventilated with a Harvard respirator delivering room air with a tidal volume of 15 ml/kg. Thoracotomy was performed through the fifth left intercostal space. After the lungs were retracted and the heart suspended in a pericardial cradle, the left anterior descending coronary artery was gently dissected free from adjacent epicardium immediately above the first diagonal branch approximately 2 cm from the origin of the left coronary artery (Fig. 1). Polyethylene catheters were placed in the left atrium for injections of dyes and radiolabeled microspheres, in the left carotid artery for measuring arterial pressure and for withdrawal of a reference blood sample during microsphere injection, and in the left jugular vein for administering intravenous injections.

The left anterior descending coronary artery was occluded with a Schwartz vascular clip above the first diagonal branch. All dogs received an intravenous bolus infusion of lidocaine, 1.5 mg/kg, immediately after coronary occlusion. Fifteen minutes after occlusion, regional myocardial blood flow was determined by injecting approximately 2.0×10^6 radioactive microspheres, 8 to 10 μ in diameter and labeled with cerium-141. After injection of the microspheres, 0.5 ml/kg of a 4 percent solution of sodium fluorescein was injected into the left atrium, and the epicardial region of low perfusion was determined using an ultraviolet light source at 340 mμ to detect fluorescent (perfused) and nonfluorescent (nonperfused) epicardium. If observed within 15 seconds of injection, the nonfluorescent region represents epicardial tissue with a regional myocardial blood flow of less than 0.4 $ml \cdot min^{-1} \cdot g^{-1}$ (Darsee JR, Kloner RA, unpublished observations). The nonfluorescent region always coincided geographically with the area of epicardial cyanosis observed with standard lighting.

Protocol: Thirty minutes after occlusion of the left anterior descending artery, the dogs were randomly assigned to one of three groups: (1) Group I (dogs subjected to 2 hours of coronary occlusion followed by 4 hours of reperfusion), (2) Group II (dogs subjected to 4 hours of coronary occlusion followed by 2 hours of reperfusion), or (3) Group III (dogs subjected to 6 hours of coronary occlusion). Dogs with an extremely small area of nonfluorescent epicardium (approximately less than 9 cm^2) resulting from extensive collateral flow from unoccluded vessels, and dogs having even one episode of ventricular fibrillation were excluded before the randomization. The fluorescein was completely washed out of the myocardial vessels within 30 minutes.

Six hours after occlusion, four dogs in each group had a second left atrial injection of microspheres labeled with tin-113 with the coronary clamp released. In the eight dogs with 2 and 4 hour occlusions, the clamp had already been released for 4 and 2 hours, respectively, to permit correlation of regional myocardial blood flow at 6 hours with the spatial geometry and transmural distribution of dyes (described later).

At the end of 6 hours, all dogs received a left atrial injection of thioflavin-S, 0.5 mg/kg, with the coronary arterial clamp released. Thioflavin-S is a fluorescent dye that stains capillary endothelium, and its absence was used to identify the area of no reflow. This injection was followed rapidly by a left atrial injection of methylene blue, 3 ml/kg, with the left anterior descending artery reoccluded to determine the in vivo area at risk for development of necrosis. We[7] have previously shown that myocardium not perfused by an in vivo left atrial injection of methylene blue has measured values for regional myocardial blood flow of less than 0.4 $ml \cdot min^{-1} \cdot g^{-1}$ tissue. Ventricular fibrillation or cardiac standstill was induced by barbiturate overdose and the hearts were excised rapidly and placed on ice.

Measurement of area of necrosis, area at risk and area of "no reflow": The right ventricle, epicardial fat and valve tissue were removed and the left ventricle was separated from the left atrium at the atrioventricular ring. The hearts were frozen rapidly in liquid Freon®, and the left ventricle was sliced into 5 mm thick transverse sections with use of a rotary blade and allowed to thaw. A clear glass plate was placed over both sides of each slice, and inner and outer margins of each slice were traced on a clear acetate sheet. With the aid of an ultraviolet light source (340 mμ), the areas not perfused by thioflavin-S after release of the coronary occlusion (area of no reflow) were traced on the same sheet. Then, the areas not perfused by methylene blue during coronary occlusion (area at risk) were also traced on the same acetate sheet. To determine the extent of myocardial cell injury, the slices were incubated in prewarmed (37° C) triphenyltetrazolium chloride (TTC) for 20 minutes as previously described.[8] Triphenyltetrazolium chloride stains normal myocardial tissue containing lactic dehydrogenase bright red; irreversibly injured tissue, depleted of lactic dehydrogenase, is not stained by TTC and remains pale yellow.

We have recently shown (Kloner RA, Darsee JR, unpublished observations) that as early as 6 hours after coronary occlusion, tissue that stains positive (red) in TTC dye is normal by ultrastructural examination except for partial depletion of glycogen, a finding to be expected after a 10 to 20 minute period of autolysis during incubation in TTC. In contrast, tissue just within the border of TTC-unstained (pale yellow) tissue showed the following ultrastructural features of irreversible ischemic myocardial cell injury: disruption of sarcomere register, profound glycogen depletion, subsarcolemmal and intermyofibrillar edema, swollen mitochondria

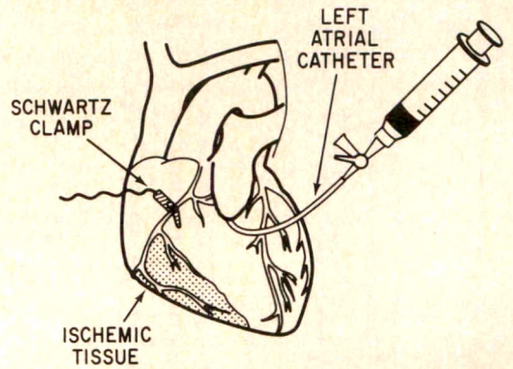

FIGURE 1. Drawing of the experimental preparation, depicting the left mid lateral region of the left ventricle. The Schwartz clamp was used to occlude the left anterior descending coronary artery and the left atrial catheter was used for injection of radioactive microspheres and dyes. The **stippled region** represents the ischemic bed.

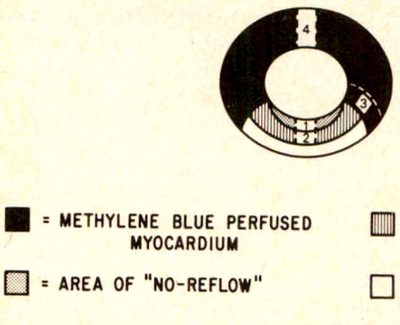

FIGURE 2. The four zones of myocardium from which tissue was dissected for analysis of regional myocardial blood flow (see text).

with disrupted cristae, and amorphous dense bodies within the mitochondria. Thus, TTC can be used to identify irreversibly injured ("infarcted") tissue as early as 6 hours after coronary occlusion, despite the absence of the usual features of necrosis on routine light microscopy. There was no evidence of partial or incomplete staining by TTC dye, and there were no zones of tissue with intermediate ultrastructural changes. Infarcted and noninfarcted areas on both sides of each slice were traced on a second clear acetate sheet.

The following values were obtained by computation using planimetric measurements: (1) the area of no reflow (A_{nr} = ratio of nonfluorescent areas to total areas of all slices); (2) the area at risk (A_r = ratio of areas not perfused by methylene blue to total areas of all slices); and (3) area of necrosis (A_n = ratio of areas not stained by TTC to total areas of all slices).

Regional myocardial blood flow: With the acetate sheet with the A_{nr} and A_r tracings placed over the TTC-stained sections as a guide, left ventricular tissue was dissected for determination of regional myocardial blood flow from the following four regions (Fig. 2): (1) area of no reflow (zone 1), (2) tissue within the area of necrosis but outside the area of no reflow (zone 2), (3) methylene blue-perfused tissue just outside the lateral border of the area at risk (zone 3), and (4) normal myocardium distant from the area at risk (zone 4). The dissected pieces of tissue were weighed (all were between 1.0 and 1.4 g), and regional myocardial blood flow and cardiac output were calculated.[9,10]

Results

Experimental groups: Of the 41 dogs, 6 were excluded because of ventricular fibrillation in the first 15 minutes after left anterior descending coronary arterial occlusion and 2 were excluded because the nonfluorescent region of epicardium after fluorescein injection was less than 9 cm^2. Of the remaining 33 dogs, 12 wer randomly assigned to Group I, 10 to Group II and 11 t Group III. None of these dogs had ventricular fibrilla tion, although several had premature ventricular com plexes and brief runs of ventricular tachycardia tha responded to administration of lidocaine. The mea body weight, total dose of anesthesia, initial and pre terminal heart rates, mean arterial pressure and tota dose of lidocaine (Group I = 120 ± 5 mg [mean ± stan dard error of the mean]; Group II = 116 ± 4 mg; Grou III = 126 ± 5 mg) did not differ statistically in the thre groups. Each dog received at least 3 mg/kg of lidocain and small supplemental doses as required. After 2 or hours of occlusion, reperfusion was not associated wit prolonged tachyarrhythmias in Group I or II, althoug several dogs had brief episodes (less than 10 seconds of ventricular tachycardia.

Myocardial fluorescence and staining: Thioflav in-S exhibited uniform fluorescence in the myocardiun (capillary endothelium) supplied by the unoccluded coronary beds and from subepicardial regions within th area at risk, but did not fluoresce from subendocardia regions within the area at risk. Methylene blue staine the myocardium transmurally in regions of the lef ventricle supplied by unoccluded coronary beds but di not stain the myocardium supplied by the occlude portion of the left anterior descending coronary artery Nonnecrotic tissue incubated in TTC stained deep red necrotic tissue appeared unstained and pale yellow.

Areas of necrosis, risk and "no reflow": The mea area at risk expressed as a percent of the left ventricl did not differ statistically (probability [p] value no significant by Student's *t* test) in Groups I (23.4 ± 3.7 percent), II (25.7 ± 2.1 percent) and III (26.9 ± 1.8 percent) (Table I). However, the three groups mani fested important differences in both the areas of n reflow (A_{nr}) and the areas of necrosis (A_n) when thes were expressed as a percent of the area at risk (A_r). Dog in Group I (2 hours of coronary occlusion, 4 hours o perfusion) had the smallest A_{nr} (11.5 ± 2.2 percent o A_r) and A_n (39.1 ± 3.2 percent of A_r). In Group II (4 hours of occlusion, 2 hours of reperfusion), A_{nr} and A_r were both larger (33.4 ± 2.8 percent and 84.5 ± 4.1 percent of the A_r, respectively; both values, $p < 0.01$ compared with values in Group I). In Group III, A_{nr} (46.7 ± 5.2 percent of A_r) and A_n (96.3 ± 1.5 percent o A_r) were even larger than in Group II (both $p < 0.01$ compared with values in Group I or II). In all dogs the

TABLE I

Relations Among Area of No Reflow, Area of Necrosis and Area At Risk Determined From Transverse Ventricular Sections

	Group I	Group II	Group III
Duration of coronary occlusion (h)	2	4	6
Duration of reperfusion (h)	4	2	0.033
Area at risk (A_r) (% total left ventricle)	23.4 ± 3.7	25.7 ± 2.1	26.9 ± 1.8
(A_n/A_r) × 100 (%)	39.1 ± 3.2*†	84.5 ± 4.1*	96.3 ± 1.5
(A_{nr}/A_n) × 100 (%)	29.4 ± 2.7*†	39.5 ± 3.6*	48.5 ± 3.8
(A_{nr}/A_r) × 100 (%)	11.5 ± 2.2*†	33.4 ± 2.8*	46.7 ± 5.2

* Statistically different ($p < 0.01$) from the mean value ± standard error of the mean in Group III by Student's *t* test. † $p < 0.01$ compared with Group II; all values for areas are mean ± standard error of the mean.

A_n = area of necrosis; A_{nr} = area of "no reflow"; A_r = area at risk.

area of no reflow was contained topographically within necrotic tissue, was always smaller than the area of necrosis and occupied its subendocardial portion (Fig. 3 and 4).

Regional myocardial blood flow: The results of measurements obtained 15 minutes after occlusion (Table II) showed no significant group differences among mean flow values in either ischemic or nonischemic tissue. Furthermore, the comparison of flow values during reperfusion measured 6 hours after occlusion with values measured 15 minutes after occlusion showed no significant increase in regional myocardial blood flow within the area of no reflow (zone 1) even with 4 hours of reperfusion. However, the necrotic tissue just outside the border of the area of no reflow (zone 2) in Groups I and II showed a rise in regional myocardial blood flow after reperfusion to at least 71 percent of values in normal tissue, even though this tissue remained necrotic (Fig. 5). Although this improvement in regional myocardial blood flow was not as striking in necrotic tissue in Group III, there was an increase over values obtained 15 minutes after occlusion.

Discussion

Four conclusions can be drawn from this study: (1) The area of no reflow during reperfusion is smaller than,

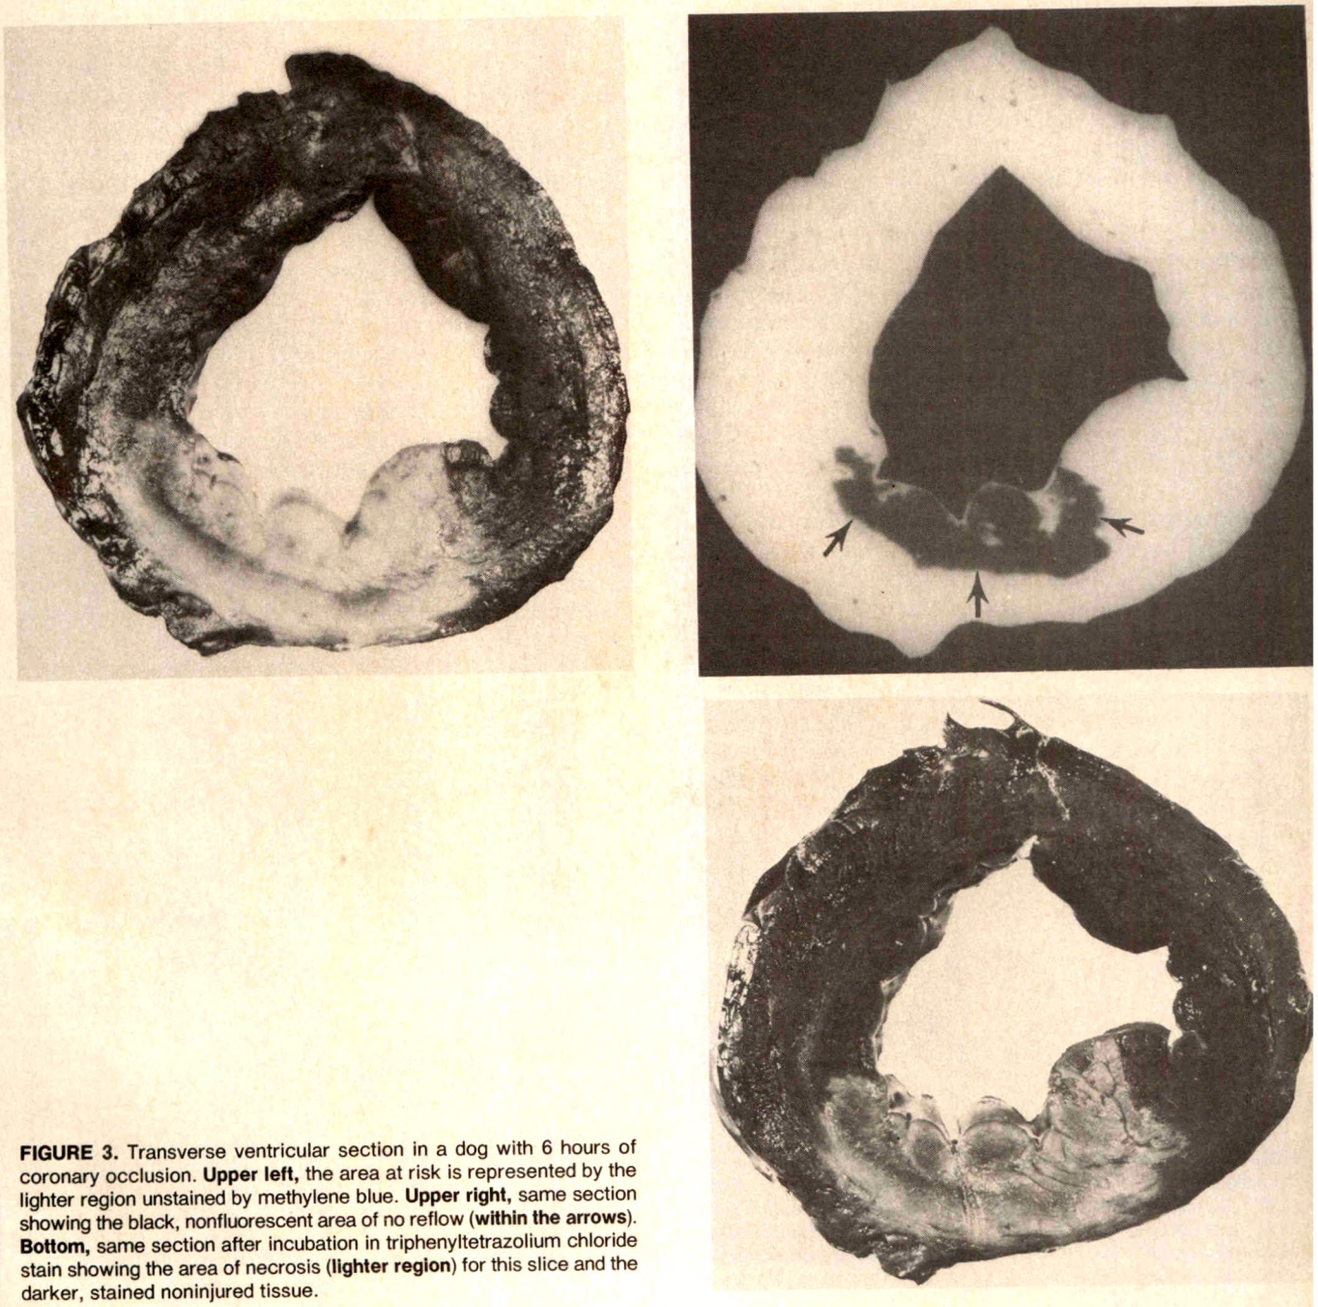

FIGURE 3. Transverse ventricular section in a dog with 6 hours of coronary occlusion. **Upper left,** the area at risk is represented by the lighter region unstained by methylene blue. **Upper right,** same section showing the black, nonfluorescent area of no reflow (**within the arrows**). **Bottom,** same section after incubation in triphenyltetrazolium chloride stain showing the area of necrosis (**lighter region**) for this slice and the darker, stained noninjured tissue.

Zones 1, 2, 3 and 4 are as depicted in Figure 1.

and contained within, the borders of the area of necrosis; (2) the area of no reflow is not a time-limiting factor determining the extent to which reperfusion or revascularization can salvage ischemic myocardium because it is surrounded by tissue that is necrotic; (3) although regional myocardial blood flow does not increase during reperfusion in necrotic tissue within the area of no reflow, improvement in flow does occur in surrounding necrotic tissue, thus suggesting that the microvasculature in this region remains intact; and (4) reperfusion does not appear to increase the quantity of ischemic tissue that becomes necrotic because coronary occlusions of briefer duration followed by reperfusion resulted in substantially less necrosis after 6 hours than did longer occlusions with briefer periods of reperfusion.

Efficacy of reperfusion in preserving ischemic myocardium: There are many methods of protecting ischemic myocardium from necrosis in animals during experimental coronary occlusion or in patients with acute myocardial infarction.[2,11–13] The most direct experimental approach to the preservation of myocardial cells has been to increase the supply of oxygen and metabolic substrates by restoring or at least improving blood flow to the occluded vascular bed. However, conflicting results regarding the efficacy of reperfusion have been reported. Maroko et al.[14] showed that after 3 hours of coronary occlusion in anesthetized dogs, reperfusion was accompanied by significantly less depression of myocardial creatine kinase activity and histologic necrosis than those found in dogs with permanent occlusion. Reimer et al.[15] also showed that reperfusion after 40 minutes to 6 hours of coronary occlusion resulted in significantly smaller myocardial infarcts than those found with permanent coronary occlusions of 2 to 4 days' duration. Constantini et al.[16] reported that, in dogs subjected to permanent coronary occlusion for 7 days, ventricular function remained depressed throughout the 7 day period and infarcted area averaged 32 percent of the left ventricle. In dogs with 3 hours of coronary occlusion followed by 7 days of reperfusion, ventricular function gradually returned to preocclusion values and the infarcted area was only 14 percent of the left ventricle.

Not all studies have shown that reperfusion is beneficial. For example, in intact conscious dogs Mathur et al.[17] produced coronary occlusion that was either permanent for 7 days or of 2 or 5 hours' duration and followed by reperfusion for 7 days. They found that the dogs with reperfusion were more likely to have arrhythmias, earlier development of electrocardiographic Q waves and accelerated hemodynamic deterioration in the postreperfusion period. In another study[18] re-

FIGURE 4. Representative drawings of the topographic relations among the area of no reflow (**stippled region**), the area of necrosis (**hatched region plus the stippled region**) and the ischemic area at risk (**white region plus the area of necrosis**) for the three groups of dogs. The area of no-reflow was always smaller than, and contained within, the area of necrosis.

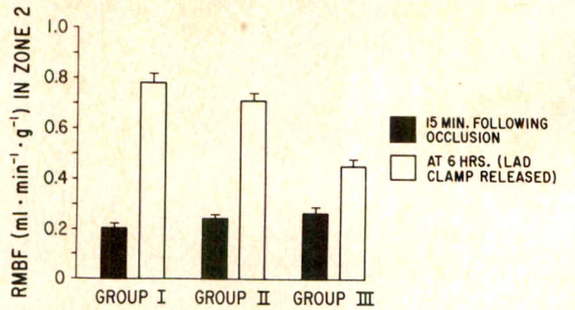

FIGURE 5. Comparison of values for regional myocardial blood flow (RMBF) 15 minutes after occlusion with values obtained after 6 hours with the left anterior descending (LAD) coronary arterial clamp removed. In all three groups of dogs, the increase in regional myocardial blood flow in zone 2 was significantly greater at 6 hours even though the tissue was necrotic.

perfusion after 3 hours of coronary occlusion in the pig resulted in extensive intramyocardial hemorrhage and no evidence of improvement in myocardial function. Hemorrhagic areas in the heart were found at necropsy in patients who underwent coronary bypass surgery in the first 7 days after myocardial infarction.[19] Ultrastructural evidence of apparent acceleration of necrosis and explosive cell swelling were described in severely ischemic tissue after reperfusion[20]; however, because this phenomenon occurred only in irreversibly injured tissue its significance is uncertain. Reperfusion did not seem to enlarge the area of necrosis, but only accelerated the process within a given quantity of irreversibly injured tissue.

The area of no reflow: One factor influencing the effects of reperfusion was not examined in these previous studies: the no reflow phenomenon, which was observed in the anesthetized dog with a temporary occlusion of the left circumflex coronary artery.[6] After 40 minutes of ischemia plus arterial reperfusion, injected fluorescent dyes were evenly distributed throughout the damaged tissue. In contrast, when reflow was allowed after 90 minutes of ischemia, portions of the inner subendocardial half of damaged myocardium (in the posterior papillary muscle) were not perfused by the dyes. Electron microscopy of this poorly perfused tissue showed severe capillary damage, decreased numbers of pinocytic vesicles, intraluminal fibrin thrombi and extravascular fibrin deposits and erythrocytes. Myocardial cells were swollen in both poorly perfused and well perfused irreversibly injured tissue. Contraction bands and intramitochondrial calcium accumulation were prominent features of irreversible injury with reflow at 40 minutes but were not noted after 90 minutes of ischemic injury in regions with poor perfusion. However, the exact spatial relations among the area of no reflow, the area of necrosis, and the area of potentially salvageable myocardium within the ischemic area at risk were not determined in the previous study. In the present study, the area of no reflow was always subendocardial and confined well within the limits of myocardial cell necrosis as determined by the TTC technique. Portions of the outer myocardial wall within the area at risk received significant reflow that resulted in subepicardial myocardial salvage.

Reperfusion and role of microvascular damage: Although the results of experimental studies of the efficacy of reperfusion have been contradictory, the quantity of tissue salvageable by reperfusion appears to be determined primarily by the length of occlusion and is not influenced by the presence of tissue that is no longer perfusable. This conclusion is consistent with other observations in our laboratory[21] showing that in dogs subjected to coronary occlusions of only 20 minutes' duration, ultrastructural evidence of myocardial cell injury preceded evidence of microvascular damage. Both myocardial cell injury and microvascular damage progressed between 40 and 90 minutes of occlusion, but microvascular damage remained confined within areas that already showed severe myocardial cell injury, thus suggesting that microvascular damage was not a primary cause of myocardial cell injury. In a study of closed chest dogs subjected to 5.5 hours of coronary occlusion and 30 minutes of reperfusion, Fishbein et al.[22] found that the extent of hemorrhage and vascular injury evaluated histologically was less than the extent of myocardial infarction evaluated with both triphenyltetrazolium chloride-staining and histologic study, and was contained within the central and subendocardial portions of the infarcted tissue. They concluded that reperfusion hemorrhage occurs only within infarcted tissue manifesting severe vascular injury before reperfusion and that hemorrhage with reperfusion does not increase myocardial infarct size.

Clinical implications: Whether the no reflow phenomenon occurs in human patients has not yet been determined. With the current interest in the use of pharmacologic agents that increase blood flow to the ischemic bed, and in the light of recent reports of successful and beneficial early revascularization,[23] the presence of a no reflow phenomenon in human subjects could have important clinical implications. Damaged tissue that cannot be reperfused would be uninfluenced by any form of drug therapy or by flow provided by coronary bypass grafting. However, because this nonreperfusable region appears to occupy a portion of a larger surrounding necrotic zone, its effects on the salvageability of surrounding tissue are probably negligible. The perfusable part of the necrotic zone is also not likely to be influenced by interventions, although its rate of healing may be affected. The ischemic tissue outside the area of necrosis is the region of myocardium on which coronary vasodilators, early revascularization surgery and other preservation efforts will have their most profound influence. The ability to preserve ischemic myocardium depends on the efficacy of the individual agent, the time of its administration and the quantity of ischemic but still viable tissue. The latter is influenced primarily by the duration of the period between the onset of ischemia and the time of the intervention, and not by the existence, distribution or spatial geometry of the no reflow phenomenon.

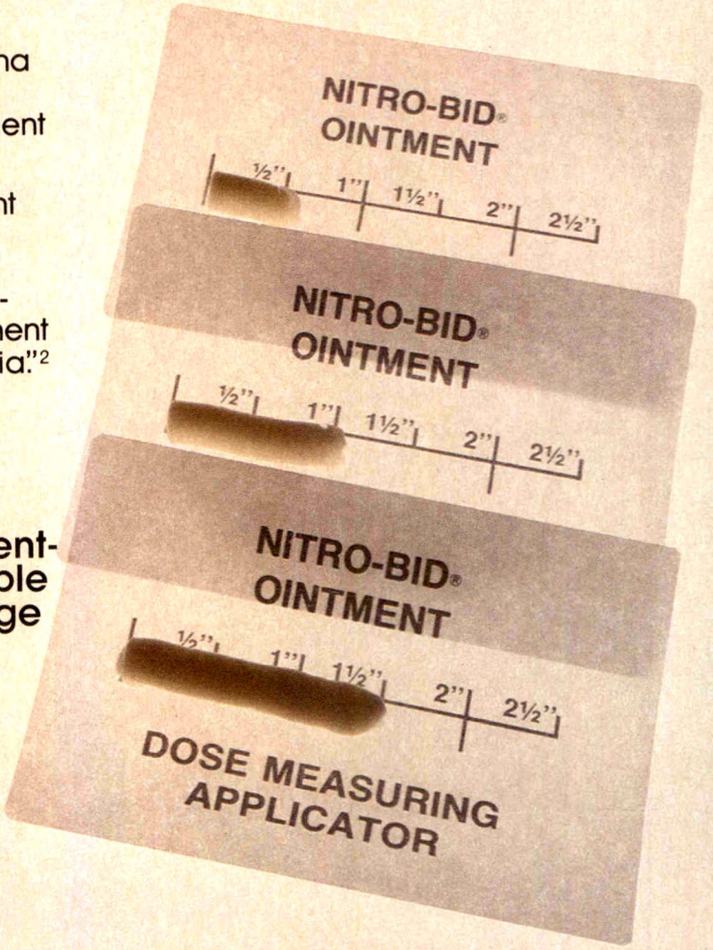
In angina pectoris...

NITRO-BID®
(2% nitroglycerin)
Transdermal Ointment



For prolonged prophylactic action

"Cutaneous administration of Nitroglycerin ointment (NITRO-BID®) in patients with angina pectoris exhibits prolonged action with evidence of pharmacological activity evident up to eight hours after application."[1]

"...data indicate that nitroglycerin ointment (NITRO-BID®) exerts profound reduction of peripheral arteriolar and venous tone with resultant alterations in left ventricular hemodynamic variables which afford enhancement of exercise tolerance and reduced ischemia."[2]

Patient-titratable dosage

Brief Summary:

Description: Nitroglycerin 2% (glyceryl trinitrate) and lactose in a special absorptive lanolin and white petrolatum base.

Action: Nitroglycerin is continuously absorbed through the skin into the circulation, thus exerting prolonged vasodilator effects.

Indications: For the prevention and treatment of angina pectoris due to coronary artery disease.

Contraindications: In patients known to be intolerant of the organic nitrate drugs.

Warnings: In acute myocardial infarction or congestive heart failure, nitroglycerin ointment should be used under careful clinical and/or hemodynamic monitoring.

Precautions: Symptoms of hypotension, particularly when suddenly arising from the recumbent position, are signs of overdosage. When they occur, the dosage should be reduced.

Adverse Reactions: Transient headaches are the most common side effect, especially at higher dosages. Headaches should be treated with mild analgesics, and nitroglycerin ointment continued. Only with untreatable headaches should the dosage be reduced. Although uncommon, hypotension, an increase in heart rate, faintness, flushing, dizziness, and nausea may occur. These all are attributable to the pharmacologic effects of nitroglycerin on the cardiovascular system, but are symptoms of overdosage. When they occur and persist, the dosage should be reduced.

Dosage: Usual dose is 2 inches (50mm), as squeezed from the tube, every eight hours. Some patients may need 4 to 5 inches (100 to 125 mm) and/or application every four hours. Optimal dosage should be based upon clinical response, side effects, and effects of therapy upon blood pressure. Consult full product disclosure before prescribing.

x Phased Array Real Time Imaging System

namically focused 2-D sector scanner featuring unique 32 channel formance. Plus two sector-derived M-modes and a totally inde-ndent M-mode. Compact, electronically steered, lightweight trans-cers. Optional heart sound/pulse and respiration module. Integral, vanced design Sony® Beta format video cassette recorder. Simulta-ous 2-D and M-mode black and white hard copy. And more.

x Cardio 80® Graphics Analyzer

eractive quantitative analysis of two-dimensional images, M-mode nocardiograms and other cardiodiagnostic data. 2-D analysis from play screen video or hard copy. Immediate printout of results. User grammable for analysis of research and special applications data. d more.

Here's how Irex breaks the barriers

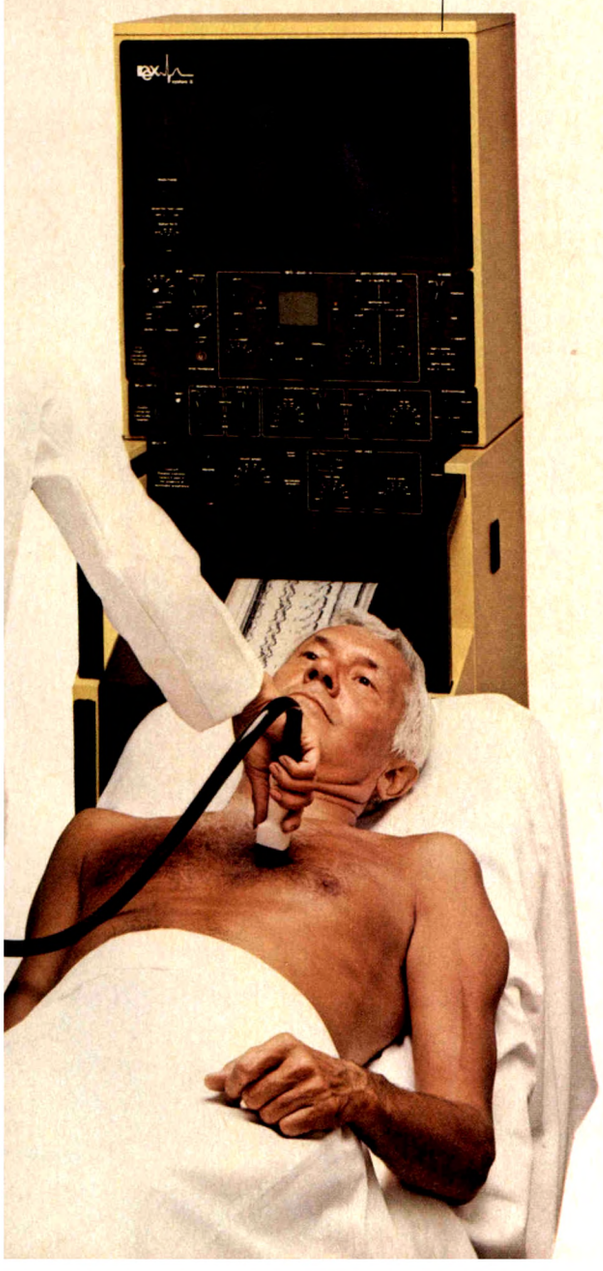
Technology. Innovative recording and display systems specifically designed for the cardiologist. Flexible, highly sensitive echo amplifier. Dynamically focused phased array. Ultrahigh resolution. Microprocessor control. State-of-the-art, phased array transducers. Software updating. High-speed digital scan conversion. All Irex designed. All Irex built. So you get leading-edge performance for improved diagnostic images.

Versatility. Broadest range of cardiac diagnostic capabilities in each Irex system. Highly flexible signal processing controls. So you can perform and analyze the study you want, the way you want to do it.

Mobility. Compact, durable systems that go where you need them, when you need them.

Commitment. The Irex commitment assures quality, reliability, continuing attention; prompt service from factory-trained Irex representatives; on-site training. So you get the most out of your Irex system.

Value. Irex systems give you features and sophistication that would cost you thousands more elsewhere.



Breakthrough technology at breakthrough price is what Irex echocardiography is all about. Return the coupon today for more ultra-exciting information.

IREX

Innovators in echocardiography

Irex System II M-mode Echocardiograph
Today's leading M-mode echocardiographic system. The Irex time-tested and proven black and white recorder. Versatile user-oriented controls. High-sensitivity, noise-free echo amplification. Additional multichannel capability for diagnostic phonocardiograms, external pulse waves and auxiliary inputs. Expandable for future applications. All Irex innovations. And, yes, more.

NEW
KLOTRIX®
(POTASSIUM CHLORIDE)
SLOW-RELEASE
TABLETS 10 mEq
For real people with compliance problems
once a day for prophylaxis–
twice a day for therapy*
KLOTRIX has more potassium chloride than
sugar-coated slow-release KCl tablets.
This means fewer tablets per day for better
patient compliance. The KLOTRIX regimen fits
into the busy lives of real people.

...in the real world of soaring prices
25% lower in cost
LOTRIX® (potassium chloride), the
conomical slow-release KCl supplement,
an save your patients as much as 25%.
LOTRIX is priced to please in this world of
oaring prices.

NEW KLOTRIX®

(POTASSIUM CHLORIDE)
SLOW-RELEASE TABLETS 10 mEq

DESCRIPTION KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS— BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with potassium-sparing diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram and clinical status of patient.
